Glossary

Glossary of Terms Frequently Used in the Nevada Comprehensive Bird Conservation Plan

Aerial	In this plan, refers to the foraging habit of catching prey items on the wing (e.g., Common Poorwill catching moths in the air)
Aquatic	In this plan, usually refers to plants or prey items that are fully submerged under water (or birds dependent on open water)
Area Requirements	These include all known data on minimum patch size, recommended patch size, and territory or home range sizes to provide a scale for effective conservation action
Arthropod	Invertebrate with hard exoskeleton, including insects, spiders, centipedes, millipedes, crabs, and others, and includes their soft immature stages
Benthic	In this plan, refers to prey items that are buried in the soil substrates of wetlands or wet meadows
Clonal; Clone	Refers to plants that spread vegetatively, usually through the root system (e.g., aspen)
Colonial	Refers to birds (or other biota) that occur in clusters during all or part of their life stage; e.g., colonial waterbirds that nest in close proximity to one another
Conservation Priority	In this plan, all bird species defined as either Conservation Species or Stewardship Species
Conservation Species	In this plan, all species that are targeted by conservation efforts because of regional concerns, such as population declines, habitat threats, or restricted population sizes
Crepuscular	Describes animals that are primarily active during the twilight hours of dawn and dusk (e.g., Common Poorwills)
Dabbler	Refers to waterbirds that feed on aquatic prey or plant material while floating at the water surface, without diving; these species are often associated with shallow waterbodies
Diurnal	Describes animals that are primarily active during the daylight hours (e.g., Lewis's Woodpecker)
Diver	Refers to waterbirds that acquire aquatic prey and plant material by diving under water; these species are often associated with intermediate or deep water depths
Emergent	Refers to vegetation that is rooted under water but has significant growth above the water surface

Glossary

Forb	Broadleaved herbaceous plant species, including typical wildflower species and other, less showy cousins
Gleaning	Refers to foraging habit of picking prey items from the surface of a substrate (usually foliage)
Graminoid	Non-broadleaved herbaceous species, including grasses, sedges, and rushes
Granivorous	Feeds primarily or exclusively on seeds
Habitat	Term describing environmental requirements or suitable environments of one or more species of birds (including, but not restricted to, vegetation parameters); in this plan, often used interchangeably with “habitat type”
Habitat type	Bird habitat type, loosely defined as a major land cover type or local setting providing the basis for a unique bird assemblage; in this plan, often used interchangeably with “habitat”
Hemi-marsh	A marsh with 30 - 60% cover of emergent vegetation, large open water areas, and areas where small patches of emergent vegetation and open water are interspersed; ideal for many Priority bird species
Herbivory	Feeds primarily or exclusively on plant material
Herbaceous	All non-woody plants, including graminoids, forbs, and emergent aquatic plants such as cattail and bulrushes
Home Range	Area of activity by one breeding pair or vagrant during their stay in Nevada; home ranges are not actively defended against intruders
Important Bird Area	Nationally recognized hotspot for bird conservation, featuring a variety and abundance of conservation priority species; program administered by Audubon Society
Indicator species	Bird species that are not themselves conservation priorities, but only occur in intact habitat conditions that are presumed to be suitable for a majority of the native bird community; species selected based on expert opinion
Insectivorous	Feeds primarily on invertebrates, including insects, spiders, other arthropods and worms
Invasive plants	All plant species that have a tendency to colonize and dominate native plant communities in disturbed states, including noxious weeds, exotics, and some native species
Invertebrate	All animals that are not vertebrates, including insects, spiders, worms, clams, and crustaceans

AR063167

Glossary

Key Conservation Area	Regions or sites that are known to be particularly important to the species and in which conservation action is likely most effective; areas for protection are important for preserving existing populations, and areas for restoration are those regions where populations may be recovered through conservation and restoration
Landscape	The wider area beyond the habitat patch an organism occurs in; the mixture of cover types and other elements in this area, the ways an organism uses them, or the ways in which they affect the organism
Mesic	A relative term referring to plants or plant communities with greater access to water; although usually referring to conditions between xeric deserts and hydric wetlands, in this plan it is often used to refer to the entire wetter part of the continuum, including riparian and wetland habitats
Mosaic	In this plan, refers to habitat patchiness within a major land cover type; for instance, a grebe may use dense marsh vegetation for breeding, but it is important that open water is available for foraging within the same waterbody; the term can also refer to the arrangement of land cover types in the wider landscape
Nevada Bird Count	Statewide landbird monitoring program administered by GBBO since 2002; addresses long-term trend monitoring for all birds, but is most effective for diurnal landbirds
Nocturnal	Describes animals that are primarily active at night (e.g., Flammulated Owl)
Patch Size	Area of land in appropriate habitat required by a breeding pair or migrant; minimum patch size refers to the area required to attract at least one individual or pair; recommended patch size refers to the area estimated to be minimally necessary for achieving conservation effectiveness
Phenology	Particular pattern of a sequence of events; for instance, nesting phenology can be described with seasonal timing of onset, timing of peaks, and duration of breeding activities
Phreatophyte	A deep-rooted plant that obtains its water from the water table or the layer of sil immediately above it
Piscivorous	Feeds primarily or exclusively on fish
Predatory	In this plan, refers to birds that hunt primarily for terrestrial vertebrates
Probing	Refers to retrieving prey or other food items by inserting the bill into substrate (usually soil or bark)
Riparian	Associated with streams and rivers; usually short for “riparian habitat”, which refers to plant and insect communities and physical conditions associated with streamsides or river floodplains with direct access to water

Glossary

Seral stage	Refers to successional stage of particular plant or plant assemblage
Special Status Species	These include species that are not included as conservation species, but for which at least a moderate conservation concern, major research needs, or written agency policies exist
Species Concerns	Refers to reasons why the species was ranked as a Conservation Priority or Special Status species
Site Fidelity	Estimated degree of dependence on historically occupied sites; if ranked high, birds are unlikely to use alternate sites if their historic location is destroyed; if ranked low, birds are not particularly tied to any location on the landscape and readily colonize new sites if appropriate habitat becomes available
Stewardship Species	In this plan, Priority species that are not ranked as Conservation Species, but for which Nevada has a significant responsibility for maintaining populations because ≥ 20% of their global population occurs in the state
Stressor	Process or activity that can have negative effects on bird populations or bird habitats
Territory Size	Area used and defended by a breeding pair, or by a migrant during its stopover in Nevada; differs from home range in that territory only refers to the actively defended area, usually around the nest or an important food resource
Uplands	Refers in this plan to non-mesic habitat types, such as salt desert, Mojave scrub, Joshua tree, coniferous forest, pinyon-juniper, etc.; the distinction is made to distinguish from wetland, riparian, open water, or aspen, which display vegetation that either directly or indirectly accesses water most of the time

WAFWA	Western Association of Fish and Wildlife Agencies
WMA	Wildlife Management Area (managed by NDOW)

Appendices

Appendix 1: Methods

Selection of Priority Species

General Selection Criteria

Priority bird species for this plan were selected based on a set of systematic qualifying criteria. By default, a species was given priority status if it: 1) regularly occurs in Nevada (*Appendix 2*), and 2) meets one or more of the following criteria as determined by agencies, bird conservation initiatives, legal mandate, or Nevada stewardship responsibility:

a) *Audubon Watchlist*: Red or Yellow List rankings
b) *Partners in Flight North American Landbird Conservation Plan* (Rich et al. 2004): Watch List ranking
c) *Intermountain West Waterbird Conservation Plan* (Ivey and Herziger 2006): High or Moderate Concern rankings
d) *Intermountain West Regional Shorebird Plan* (Oring et al. 2000): Critically Important or Very Important rankings
e) Pacific Flyway portions of the *North American Waterfowl Management Plan* (USFWS 1986, 1998): High-ranking species with significant presence in Nevada
f) *Nevada Department of Wildlife Upland Game Species Management Plan* (NDOW 2008): High Concern ranking
g) Listed by USFWS under the Endangered Species Act (ESA), including candidate species
h) Protected under the Bald and Golden Eagle Protection Act
i) Significant species stewardship responsibility: ≥ 20% of the estimated global population occurs in Nevada.

Priority species were divided into three different categories, following the usage of Chase and Geupel (2005). All Priority species, regardless of category, are treated in an individual species account. Each category is described below.

Conservation Priority Species

Conservation Priority species require active conservation efforts, such as habitat protection, habitat restoration, special or enhanced monitoring efforts, further research, or additional public education. Generally, there are tangible reasons for concern about a Conservation Priority species, which may include:

a) Known or probable population declines
b) Dependence on restricted habitats
c) Small population size
d) Habitat threats

Although the habitat-based conservation strategies presented in this plan were designed to benefit entire bird communities, they were initially motivated by the needs of Conservation Priority species.

Stewardship Species

There were four species that qualified for Priority status based only upon the fact that Nevada is estimated to support ≥ 20% of global population. These were designated as Stewardship species. We believe these Stewardship species deserve priority consideration in Nevada because significant threats in the state can have significant impacts on the entire species. In some cases, Conservation Priority species also had high Nevada stewardship percentages; this is noted in the "Conservation Profile" tables within the species accounts.

Special Status Species

The Special Status designation was used for three species that did not qualify as Conservation Priority or Stewardship Species, but that still merited attention in this plan. Two of these species, Bald Eagle and Peregrine Falcon, have recently been de-listed under the ESA and require ongoing population monitoring. The third species, Burrowing Owl, was included in this category because its conservation status is currently difficult to assess. On the one hand, there are conservation concerns about Burrowing Owls in many western states, but on the other, we could find no evidence of population declines or serious threats in Nevada. We anticipate being able to determine whether or not Burrowing Owl should be assigned Conservation Priority status in some future revision of this plan.

Exceptions

Northern Goshawk and Ferruginous Hawk were included as Conservation Priority species despite not formally qualifying under the guidelines listed above. Both are considered priority species by management agencies in Nevada (USFS, BLM, NDOW), and the Nevada PIF working group felt that their omission from the regional planning documents listed above was an oversight that should be corrected in this plan.

Sources of Information

In preparing this plan, we reviewed and synthesized many sources of information about the status, ecology, and management of Priority species and their habitats in Nevada. We relied most heavily on the following set of sources that were particularly well-suited to the needs of the plan:

Published Sources

Birds of North America (BNA) Species Accounts (Poole and Gill 1992-2002; cited individually in the *Literature Cited* section): This catalog of species accounts generally features an exhaustive literature review and synthesis of knowledge about every North American bird. As such, it is often the best source of information about a given species' ecology, distribution, habitat use,

breeding and foraging habits, migration patterns and phenology, population trends, threats, and conservation needs. In practice, not all species accounts cover these topics with equal thoroughness, and Nevada-specific information was available for some species but not for others.

Partners in Flight North American Landbird Conservation Plan (Rich et al. 2004): The continental Partners in Flight (PIF) plan provided global population estimates for landbirds, which were needed for estimating percent of global population size present in Nevada. Global population estimates were based on an analysis of Breeding Bird Survey (BBS) data for the North American portion of a species' distribution. These global estimates were stepped down to the state level by Peter Blancher and colleagues, which provided us with one source of statewide landbird population estimates for Nevada, which we referred to as the "PIF estimate." [These estimates can be found online at the Partners in Flight Landbird Population Estimates Database: http://rmbo.org/pif_db/laped/] Because Nevada has only a few historically-active BBS routes from which to extrapolate, the stepped-down statewide population estimates may be unreliable for some species.

Intermountain West Regional Shorebird Plan (Oring et al. 2000): This regional plan was created under the umbrella of the U.S. Fish and Wildlife Service's *U.S. Shorebird Conservation Plan* (Brown et al. 2001). It provides an excellent source of information about the status, trends, population sizes, hotspots, and conservation issues regarding Nevada's shorebirds.

Intermountain West Waterbird Conservation Plan (Ivey and Herziger 2006): This regional plan was created under the umbrella of the "Waterbird Conservation for the Americas Initiative," which produced the *North American Waterbird Conservation Plan* (Kushlan et al. 2002). It provides an excellent source of information about the status, trends, population sizes, distributions, and conservation issues of Nevada's nongame waterbirds.

Nevada Upland Game Species Management Plan (NDOW 2008): This plan was consulted as the best single source of information about the status, trends, population sizes, distributions, and management concerns of Nevada's upland game birds.

Other published sources

We expended considerable effort to glean as much information as possible from scientific journals and agency reports. We gave the greatest weight to quantitative, species-specific conservation or habitat related data from Nevada or immediately adjacent regions. Next in priority were sources relevant to wider regions (such as the Intermountain West) that had some applicability to Nevada. These are cited throughout the plan with full references collected in the *Literature Cited* section.

Data Sources

Nevada Bird Count

The Nevada Bird Count (NBC) was the most heavily used source of data for this plan. Due to its length, a full description of this program is presented at the end of this section (p. App-1-5).

Appendices

Breeding Bird Survey (BBS) Trends and Analyses

The latest trends analyses of BBS data (Sauer et al. 2008; http://www.mbr-pwrc.usgs.gov/bbs/) were consulted to determine regional and continental population trends for the period 1966 – 2007. For most species, reliable Nevada-specific trends were not available, but trend estimates were often available for wider geographic regions that included Nevada.

Nevada Breeding Bird Atlas Project

The Nevada Breeding Bird Atlas project, conducted by the Great Basin Bird Observatory (GBBO), involved systematic statewide data collection to document all confirmed and probable breeding bird species during the period 1997 – 2000 (see Floyd et al. 2007 for details). The database that was generated by the atlas contains over 30,000 bird observation records, and it provides one of the major sources of data on bird distribution, breeding status, and breeding phenology in Nevada. The atlas database is available upon request to GBBO. Atlas methods were well-suited for surveying most diurnal landbirds and some secretive species, such as owls, but they were less effective for birds that tend to congregate in large numbers in widely scattered sites (e.g., many shorebirds, waterbirds, and waterfowl), for upland game birds with sporadic, disconnected distributions, and for a handful of other bird taxa that are difficult to survey with a standard multi-species protocol (e.g., nightjars, hummingbirds). Many of the species that were under-surveyed by atlas methods were better covered by data sets residing at the federal and state wildlife agencies, which were also consulted for this plan.

Nevada Department of Wildlife Diversity Database

The Nevada Department of Wildlife maintains a database of wildlife occurrence records that are collected during the course of the agency's work across the state. This database, combined with databases from the Nevada Bird Count and the Nevada Breeding Bird Atlas project, was used for determining distribution patterns and creating range maps (see "Range Maps" section, below).

Site-Specific Waterbird and Shorebird Surveys

Site-specific monitoring of waterbirds and shorebirds is routinely performed on National Wildlife Refuges by USFWS refuge staff and on Nevada's State Wildlife Management Areas by NDOW staff. Additionally, NDOW conducts annual aerial surveys of colonial waterbirds and waterfowl, and seasonal migration surveys of shorebirds in the Lahontan Valley area (Larry Neel, *pers. comm.*). Collectively, these data sources allow us to estimate waterbird and shorebird numbers, abundance peaks, distributions, and, in some cases, trends. These data sources were compiled by Larry Neel (NDOW) for use in this plan.

Aquatic Bird Count

The Aquatic Bird Count is a GBBO program for aquatic bird monitoring throughout Nevada. Although this program's survey activities vary in scope from year to year, it has generated a database that is useful in helping to determine the distributions and seasonal presence of

waterfowl, waterbirds, and shorebirds in many areas of the state. The Aquatic Bird Count database is available upon request to GBBO.

eBird

eBird (www.ebird.org), an offering of the Cornell Laboratory of Ornithology and partners, is a web-based repository of observations and sightings uploaded by birders and ornithologists from across the globe. Its visualization tools are especially useful for determining seasonal presence, phenology, and distribution of birds across any area of interest.

Other

Other data sources consulted for particular species included:

a) Raptor nest surveys conducted by NDOW, USFS, BLM, and their partners (including the "Great Basin Raptor Nest Survey" program coordinated by HawkWatch International; see www.hawkwatch.org/conservation-science/raptor-nest-survey)
b) Winter raptor surveys conducted by NDOW and partners (Southern Nevada Water Authority, GBBO)
c) Special surveys conducted for species of interest (including Yellow-billed Cuckoo, Southwestern Willow Flycatcher, Peregrine Falcon, Yuma Clapper Rail, Snowy Plover, Bendire's Thrasher, and Flammulated Owl) by a variety of agencies, organizations, consultants, or academic scientists

Nevada Bird Count (detailed program description)

Overview: The Nevada Bird Count (NBC) is a standardized statewide landbird monitoring program that was initiated by the Great Basin Bird Observatory in 2002. Like the atlas project, it is focused on the breeding season, but NBC uses a more quantitative approach to sampling in order to more effectively detect long-term population trends (e.g. Bart 2005a). NBC monitoring has been conducted every year since program inception, and its dataset at the time this plan was prepared included eight years (2002-2009) of monitoring results from 546 transects. As such, it provides the most useful single source of information about the distributions, habitat relationships, population sizes, and densities for Nevada's landbirds.

The NBC uses a standard point-count protocol combined with area search/spot-mapping surveys in a double-sampling effort, in order to obtain detectability estimates for as many species as possible. It is an "all-bird" protocol, meaning that all species detected during a survey are recorded, but detection rates are best for small diurnal landbirds, such as songbirds, woodpeckers and their allies, and similar species that are readily visible or detectable by sound.

The NBC dataset was heavily used in the preparation of this plan, especially for generating:

a) Nevada population size estimates
b) Density estimates by habitat type
c) Statistical analyses of habitat associations

d) Range maps, in combination with atlas data and NDOW data, as described above

NBC Study Design: The NBC sampling plan is habitat-stratified (see "Habitat Types" section below for a complete description of the habitat designations used). To the extent possible, transects were randomly selected within each habitat type with the help of GIS land cover maps, although adjustments were sometimes required due to access issues or poorly mapped habitat types. All transects were located off-road, except in sites where roads could not be avoided (e.g., riparian areas in canyons), or where roads are part of the habitat type being surveyed (e.g., agricultural areas). Allocation of survey effort among habitat types was determined by conservation priorities, agency needs, and a statistical power analysis conducted during the first two years of the NBC program.

Several partner organizations and agencies were willing to integrate their ongoing monitoring efforts by adhering to NBC protocols and contributing their data to the NBC database. These partners included the Clark County Desert Conservation Program, Great Basin National Park, the USFS Humboldt-Toiyabe National Forest, NDOW, BLM, Lake Mead National Recreation Area, Southern Nevada Water Authority, the USFWS National Wildlife Refuge system, and the U.S. Bureau of Reclamation. This coordination has greatly improved the scope and statistical power of the NBC database.

NBC Survey Protocol: Full descriptions of NBC survey protocols can be obtained at http://www.gbbo.org/data.html. Briefly, NBC surveys are conducted between April 25 and June 30 in the Mojave Desert region, and between May 25 and July 10 in the Great Basin region. Each transect (location) is covered using an array of ten point-count stations. A 10-minute survey is conducted at each point, in fair weather conditions, and with all ten points of one transect completed within four hours after daybreak. All birds detected by sight and sound are recorded in three time intervals (0-3 min, 3-5 min, 5-10 min) and at three distance intervals (0-50 m, 50-100 m, > 100 m).

Detectability: Point-count data are affected by species-specific detectability, and thus the NBC protocol includes a double-sampling effort that combines areas searches with point-counts to estimate species-specific detectability (Bart and Earnst 2002). Results to date show that for moderately vocal or visible species, the 10-minute survey protocol for point counts results in a detection ratio of close to 1.0 within a 100 m distance (all birds present are detected). Therefore, all NBC-based analyses (in particular, densities and population size estimates) presented in this plan assume a detection ratio of 1.0. All cryptic species, or species groups known to be poorly sampled by NBC, are assumed to have a detection ratio of significantly < 1.0, and these species are excluded from NBC-based analyses in this plan.

Vegetation Assessments: Vegetation and habitat assessments are part of the NBC protocol, as more fully described at http://www.gbbo.org/data.html. We used NBC-derived habitat measurements for statistical analyses of habitat relationships for a small number of relatively common Priority species in this plan.

Transect Habitat Assignments: Many NBC transects were located entirely within a single relatively uniform habitat type. In order to survey habitat types that occur in small or narrow

patches, however, many transects had to cross habitat type boundaries. Rules were therefore established to ensure that a minimum amount of the target habitat type was present, and to generate an acceptable level of consistency in habitat-based analyses.

Habitat Types

Habitat types are defined, for the purpose of this plan, as distinct land cover categories that support relatively distinct bird communities. While the term "habitat" technically describes only the environmental needs of one particular species, here we embrace the less formal use of the word, where "habitat" means a major land cover type or local setting providing environmental requirements or suitable environments for a unique bird assemblage. This definition allows us to group bird species under the umbrella of shared habitat conservation strategies.

The process of selecting habitat types for this plan paralleled the processes used in the original *Nevada PIF Bird Conservation Plan* (Neel 1999) and the Nevada Bird Count (NBC) habitat stratification. For both the 1999 plan and NBC, habitat types were created by lumping together land cover types identified in the GAP vegetation map (Homer et al. 1998). For instance, several land cover types that were dominated by coniferous trees were combined into a "Coniferous Forest" habitat type (we capitalize formal habitat type designations to distinguish them from more casual references to dominant vegetation). Other coniferous land cover types were combined to form "Pinyon-Juniper" habitat. In the more recent *Nevada Wildlife Action Plan* (Nevada Wildlife Action Plan Team 2006), the same general approach was used, but it was based primarily on land cover types identified by the Southwest Regional Gap Analysis Project (SW ReGAP) mapping effort (Prior-Magee et al. 2007). We also used the same approach in this plan, but chose to consider land cover types as defined in several different mapping efforts. A more detailed description of this process is given below in the "Spatial Habitat Data" section.

The habit types designated in the four efforts described above were very similar, but there were some variations resulting from the use of different fundamental land cover types, different approaches to grouping land cover types, and different terminology. The relationships between habitat types designated in these four efforts are summarized in Table App-1-1, below.

Table App-1-1: Cross-walk of habitat types defined by four different programs / plans. 1999 Plan = original PIF bird plan (Neel 1999); NWAP = Nevada Wildlife Action Plan

This Plan	1999 Plan[1]	NBC	NWAP [2]	Short Description for This Plan
Agriculture	Ag Lands	Agriculture	Agricultural Lands	All irrigated agricultural fields and associated infrastructure
Alpine	(not included)	(not included)	Alpine and tundra	Above treeline (tundra)
Aspen	Aspen	Aspen	Aspen woodland	All aspen-dominated woodlands

Appendices

This Plan	1999 Plan[1]	NBC	NWAP [2]	Short Description for This Plan
Cliff	Cliffs and Talus	(not included)	Cliffs and Canyon	Prominent cliffs and talus
Coniferous Forest	Coniferous Forest	Coniferous Forest	Intermountain (and Sierra) conifer forests and woodlands	All mixed and pure coniferous woodlands except pinyon-juniper
Springs	(included under Wetlands/ Lakes)	(not included)	Springs and springbrooks	All spring systems that are too small to form major riparian or wetland patches
Ephemeral Wetland and Playa	(included under Wetlands/ Lakes)	(not included)	Desert playas and ephemeral pools	All wetlands without perennial, or mostly perennial, water
Great Basin Lowland Riparian	Lowland Riparian	Lowland Riparian	Intermountain Rivers and streams	Streamside vegetation and river-fed wetlands that are mostly restricted to valley floors in the Great Basin (generally < 5,500 ft or 1,800 m)
Joshua Tree	(included under Mojave Shrub)	Joshua Tree	Mojave mid-elevation mixed Desert Scrub	Mid-elevation Mojave uplands that have a significant component of Joshua tree or other *Yucca* spp.
Marsh	(included under Wetlands/ Lakes)	(included under Wetland)	Marshes	Permanent wetlands dominated by emergent vegetation, interspersed with open water
Mesquite-Acacia	Mesquite-Catclaw	Mesquite-Catclaw	Mesquite bosques and Desert washes	Mesquite and/or *Acacia*-dominated washes and bosques in the Mojave Desert

Appendices

This Plan	1999 Plan[1]	NBC	NWAP [2]	Short Description for This Plan
Mojave Lowland Riparian	Lowland Riparian	Lowland Riparian	Mojave rivers and streams	Streamside vegetation and river-fed wetlands that are mostly restricted to valley floors in the Mojave Desert and White River Valley (generally < 4,000 ft or 1,300 m)
Mojave Scrub	Mojave Shrub	Mojave Scrub	Mojave/ Sonoran Warm Desert Scrub	Low-mid elevation scrub communities of the Mojave Desert, usually dominated by creosote
Montane Riparian	Montane Riparian	Montane Riparian	Intermountain rivers and streams	Streamside vegetation that is mostly restricted to montane areas (generally > 5,000 ft or 1,600 m)
Montane Shrubland	Montane Shrub and Sagebrush	Montane Shrub and Montane Sagebrush	(shared among several habitat types)	Deciduous and non-deciduous shrubs generally at or above the pinyon-juniper zone, but not including the alpine zone, including Montane Sagebrush
Open Water	Wetlands/ Lakes	(not included)	Lakes and Reservoirs	Water bodies that are usually large and have only a minor component of emergent vegetation, such as lakes and reservoirs
Pinyon-Juniper	Pinyon-Juniper and Mountain Mahogany	Pinyon-Juniper and Mountain Mahogany	Lower Montane woodlands	Pinyon-juniper dominated landscapes, including mountain

Appendices

This Plan	1999 Plan[1]	NBC	NWAP [2]	Short Description for This Plan
				mahogany components and open woodlands with shrub understory
Sagebrush	Sagebrush (including Montane Sagebrush)	Sagebrush (excluding Montane Sagebrush)	Sagebrush (including Montane Sagebrush)	Sagebrush-dominated shrublands below the pinyon-juniper zone (not including Montane Sagebrush – see Montane Shrubland)
Salt Desert Scrub	Salt Desert	Salt Desert Scrub	Intermountain cold desert scrub	Desert scrub below the sagebrush or Mojave Scrub zone, often dominated by saltbush, greasewood, and other salt-tolerant species
Wet Meadow	Wetlands/ Lakes and Montane Parkland	Wetland	Wet Meadows	Mesic graminoid-dominated meadows (sedges, rushes, grasses) that have ample access to water, but little emergent vegetation

[1] Neel (1999); [2] Nevada Wildlife Action Plan Team (2006)

The 20 habitat types listed above provide the basis for the habitat accounts presented in this plan, where we describe the physical and floristic characteristics of each habitat type, relate these characteristics to bird habitat suitability, list major threats, and recommend conservation strategies. These habitat types account for most of the surface area in Nevada. The remaining portions of the state consist mostly of developed areas (urban, suburban, rural, industrial, roads), barren areas, and exotic vegetation, none of which were considered conservation priority habitats. There are also very limited upland areas of native grassland, but they are difficult to distinguish accurately from irrigated fields or wet meadows in GIS maps, so they were not included in our habitat classification.

Appendices

Spatial Habitat Data

Overview

In order to analyze NBC data as a function of habitat, we needed to define habitat types listed above in terms of underlying land cover categories (we refer to this process as a "roll-up" hereafter), and then map the spatial distributions of each habitat type. We felt that all of the individual mapping efforts upon which the roll-ups could be based had inadequacies, and further that these inadequacies could be partly rectified by combining their more reliable features. Therefore, we used land cover categories derived from several different sources as the basis for rolling-up habitat types.

Habitat classification and mapping

We relied primarily on the multi-partner LandFire Existing Vegetation Type (EVT) map (www.landfire.gov) as a source of land cover categories. The LandFire Existing Vegetation Type (EVT) map, in particular, is thought to capture small-scale riparian features more effectively than the Southwest ReGAP map (Peterson 2008), which was a major basis for our decision. Table App-1-2 shows the sources of the land cover categories that were used for habitat type roll-ups in this plan. A detailed accounting and rationale of exactly which land cover categories were used to define each habitat type is available from GBBO upon request. Below, we describe the exceptions to the general pattern of rolling up either LandFire land cover categories.

1) Cliff and talus distribution was best mapped by the Southwest ReGAP product (Prior-Magee et al. 2007), which was used as a basis for our Cliff habitat type
2) Ephemeral Wetland and Playa habitat was mapped based on the National Wetlands Inventory (NWI) dataset (http://www.fws.gov/wetlands/) and the Nevada Natural Heritage Program's water-playa shapefile (http://heritage.nv.gov/gis/gis.htm)
3) The boundary between the Great Basin Lowland Riparian and Mojave Lowland Riparian habitat types was based on the accepted eco-regional boundary between these two regions, although this boundary may vary slightly in different products. Our ecoregional shapefile is available upon request to GBBO
4) Joshua Tree was poorly classified by LandFire and ReGAP land cover types. Instead, we used a first-generation Joshua Tree habitat map created by USGS (Todd Esque, *pers. comm.*)
5) Marshes and wetlands were captured best by the Southwest ReGAP product, which was used as a basis for the Marsh habitat type
6) Mesquite-Acacia was poorly classified by LandFire and ReGAP land cover categories. Instead, we used a map of Mesquite-Acacia habitat that was created by the University of Nevada Reno (UNR) as part of the Clark County MSHCP project (Clark County 2000)
7) The LandFire land cover categories contributing to the Mojave Lowland Riparian habitat type roll-up severely overestimated the extent of actual riparian vegetation, as determined by systematic overlays of these land covers with aerial photography. We conducted an in-depth effort to reclassify this habitat type based primarily on a stream-order determination using Arc GIS tools. Details are available upon request to GBBO

8) Montane Riparian habitat could often be separated from the two lowland riparian habitat types based on the definition of underlying land cover categories. In other cases, however, a land cover category spanned what we felt to be the reasonable boundary between the montane and lowland riparian zones. In these cases, we defined Montane Riparian habitat to occur above 1,600 m in elevation, and Lowland Riparian (either Great Basin or Mojave, depending on location) below 1,600 m (5,280 feet)
9) Springs habitat could not be distinguished from vegetation-based land covers in the ReGAP or LandFire products. Instead, we used a springs shapefile provided by BLM as the basis for our Springs map
10) Wet Meadow was best captured by examining both LandFire and ReGAP land cover categories in tandem, as both resulted in misclassifications considered individually

Table App-1-2: Source of land cover categories used in defining habitat types.

Habitat Type	Land Cover Source
Agriculture	LandFire
Alpine	LandFire
Aspen	LandFire
Cliff	ReGAP
Coniferous Forest	LandFire
Ephemeral Wetland and Playa	National Wetlands Inventory, Nevada Natural Heritage program shapefile
Great Basin Lowland Riparian	LandFire, < 1,600 m elevation threshold, and Great Basin / Mojave ecoregional boundary
Joshua Tree	USGS shapefile
Marsh	ReGAP
Mesquite-Acacia	UNR / Clark County MSHCP shapefile
Mojave Lowland Riparian	LandFire, < 1,600 m elevation threshold, Great Basin / Mojave ecoregional boundary, and manual reclassification based on stream order
Mojave Scrub	LandFire
Montane Riparian	LandFire, > 1,600 m elevation threshold
Montane Shrubland	LandFire
Open Water	LandFire
Pinyon-Juniper	LandFire
Sagebrush	LandFire
Salt Desert Scrub	LandFire
Springs	BLM springs shapefile
Wet Meadow	LandFire and ReGAP

In general, we believe that our final habitat type map was as accurate as possible, given the limitations of its underlying spatial datasets. Map accuracy is poorest for habitats that occur in small or narrow patches, including all Riparian habitat types, Wet Meadow, and Aspen. Improved mapping efforts would significantly improve our ability to analyze bird – habitat relationships.

Analytical and Statistical Methods

Bird – Habitat Analyses

For the priority songbirds in this plan that were sufficiently well sampled by the NBC, we conducted analyses of NBC data using GIS-derived transect attributes as explanatory variables. In general, we referred to this as "landscape-level" analysis, which was distinct from the microhabitat analysis described in the next section.

The first step required was to define the area effectively sampled by an NBC transect. To do this, we applied a 200 m radius buffer around each survey point, and then merged the buffered points within a given transect into a single polygon in GIS. The 200 m radius buffers were selected because they capture nearly all of the effectively surveyed area around each survey point. Significantly smaller buffers would have resulted in discontinuous transect polygons and may have under-represented the habitats that were actually used by the detected birds. Once the transect polygons were defined, they were intersected with the habitat map described in the previous section, as well as a landownership map. Attributes were then created for each transect polygon, as follows:

1) Surface area of each transect polygon occupied by each habitat type that was present
2) Shortest distance from any portion of the transect polygon to the nearest year-round water source
3) Landownership breakdown of the transect polygon

We also investigated the possibility of extracting transect attributes from maps of recent burn activity, but found that too few NBC transects were located in areas of recent burn activity to permit meaningful analysis.

We used logistic regression to analyze the model the relationships between bird presence (detection or non-detection) and habitat type or distance to water. For most of the species analyzed, data were sufficient to support up to three variables in a multivariate model. For a few of the most common species, we were able to conduct additional analyses by using abundance data in a linear regression analysis. We note these in the species accounts only if they changed the resulting conclusion. Data from the Great Basin and Mojave Desert were analyzed separately.

Microhabitat Analyses

For a few priority songbirds, we also conducted statistical analyses of bird abundance and presence as a function of detailed vegetation measurements that were collected "on the ground" as part of the NBC protocol (see www.gbbo.org/data.html). These analyses were originally presented in a GBBO technical report (GBBO 2008b), where details of these analyses are presented.

Appendices

Bird Density and Occupancy Rates by Habitat Type

For the Priority species with sufficient NBC data, we calculated average density within each habitat type. Habitat-specific densities were calculated separately for the Great Basin and Mojave Desert regions of Nevada. Density estimates were based on the actual number of birds detected within 100 m of each NBC survey point (assuming a detection probability of 1.0 within this radius), divided by the area of a 100 m radius circle. Results were then standardized to birds per 40 ha. Many transects were surveyed in multiple years, and some were surveyed multiple times within a year, and in these cases we avoided bias by using a single average density for a given transect. Averages for each transect were then averaged again to create the overall density estimate, which is presented in the species accounts along with an estimate of error. For a given species, we averaged densities only from the transects where the bird was present (i.e., zero-density transects were not used). This step was necessary to avoid skewing results for birds whose geographical range in Nevada is smaller than the spatial extent of the habitats they use. The best way to interpret our density estimates, therefore, is that they provide an indication of the average habitat-specific density of a given bird within the parts of the state where they occur.

In calculating density estimates, we considered only the single habitat type designator associated with each NBC transect. We did not create subgroups of points within transects that overlaid multiple habitat types. This created situations where a bird has a non-zero density for a habitat type that it rarely, if ever, uses. For instance, a bird that always occurs within Coniferous Forest habitat may have been counted on some Montane Shrubland transects that contained a small amount of Coniferous Forest habitat. This bird will therefore show a non-zero density within the Montane Shrubland habitat type. To allow us to better detect and interpret these anomalies, we also present "occupancy rate" in the species accounts, which are defined as the proportion of all transects of a given habit type on which the bird was detected during NBC surveys. If a bird's occupancy rate for a given habitat is very low, then its associated density estimate for that habitat type is not very meaningful.

Population Size Estimates

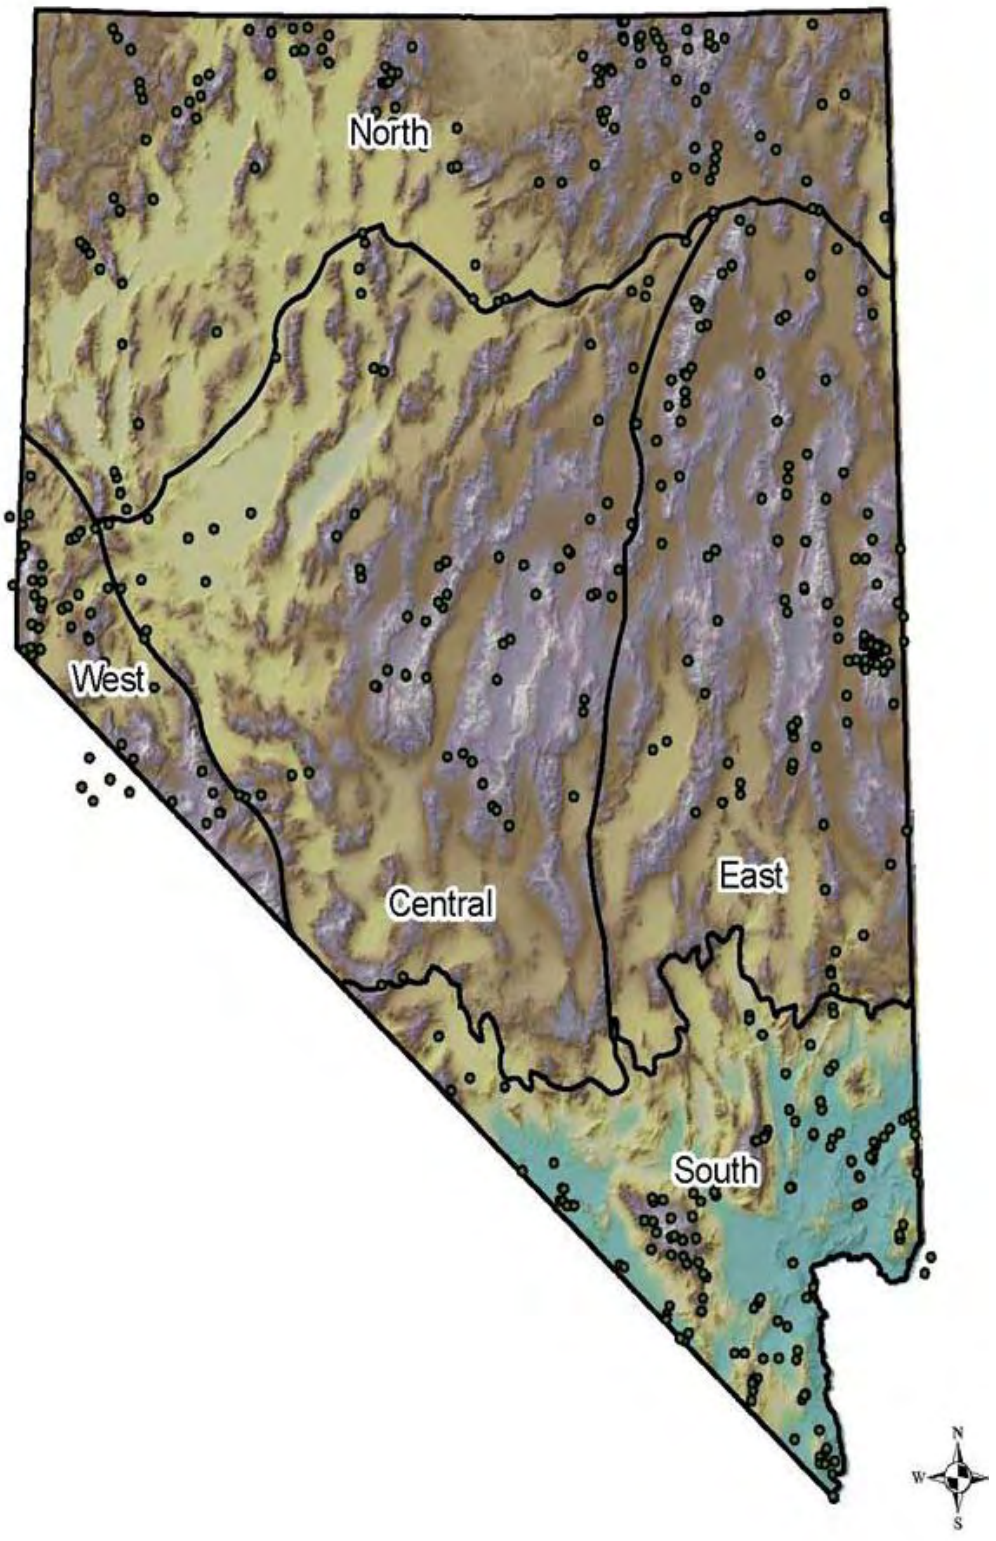
Increasingly, bird conservation initiatives have desired to have estimates of the total population sizes of bird species of concern; within a project area, within a state, or within the entire range of the species (i.e. "global"). This is an attempt to explicitly quantify current population status in relation to future conservation targets (Rosenberg and Blancher 2005). Inspired by the success of the North American Waterfowl Management Plan (USFWS 1986, 1998) in following this strategy, the major bird conservation initiatives produced in the last decade have all produced global population size estimates for their focal species (Brown et al. 2001, Kushlan et al. 2002, Rich et al. 2004), which we use as source material in this plan. Below, we discuss the sources of Nevada population size estimates used in this plan.

Partners in Flight's BBS-based Population Size Estimates

Partners in Flight generated global or continental estimates for landbird population sizes based on Breeding Bird Survey (BBS) data, as part of their development of a continental plan (Rich et al. 2004). The next step was to calculate the proportion of this population estimated to occur in

Nevada. We have taken these estimates from an unpublished spreadsheet produced by Peter Blancher (*pers. comm.*). However, BBS coverage in Nevada has been poor in past decades, and in order to produce these estimates, it was sometimes necessary to extrapolate from adjoining regions outside of the state (especially for the Sierra Nevada ecoregion). Because of this limitation, we decided to use NBC data to produce a new set of Nevada population size estimates for landbirds.

NBC-Based Population Size Estimates



The large Nevada Bird Count database provided us with an opportunity to generate new population size estimates for the state that were improvements on previously available estimates. For species that were well-sampled by the NBC, data-based population estimates were obtained by extrapolating observed bird densities across the entire landscape, while accounting for habitat-based and regional differences in these densities. As with density estimation, we considered only the single habitat type designator associated with each transect; but in contrast, we remained entirely within the framework of the original GAP-based habitat type designators used to stratify the NBC sampling plan throughout this exercise (Table App-1-1). Also in contrast to the density estimation exercise, we used all transects (including those on which a given bird species did not occur). Otherwise, we would have created inflated population size estimates by extrapolating densities that were uncharacteristic of Nevada as a whole.

Data for population size estimates were obtained from 546 NBC transects that were surveyed at variable frequencies between 2002 and 2009. These transects received an average of 2.5 surveys each during this period, generating 1376 transect-visits. Data from multiple surveys for a given transect were averaged to produce a single density estimate for each species. In order to account for the fact that many species are not distributed equally throughout the entire extent of their habitats, we divided Nevada into five geographical regions (north, west, central, east, and south) based on natural ecoregional boundaries that correspond well with most breeding ranges (Figure M1; see also Floyd et al. 2007). For example, the Gray Vireo is concentrated in Pinyon-Juniper habitat in the south region, is also present in smaller but still significant densities in the east region, and is almost totally absent from Pinyon-Juniper habitat in the remaining regions. The Pinyon Jay, in contrast, uses Pinyon-Juniper habitat statewide, except in the north region where it is mostly absent. Therefore, density estimates were generated for each unique combination of species, habitat type, and region, and those estimates were extrapolated based on the area occupied by that same habitat-region combination to arrive at a population estimate for that habitat-region. Statewide population estimates were then generated by adding all of the unique habitat-region population estimates. Systematic intra-regional variation in density within a habitat type, which no doubt occurs, was not addressed by this method, although it is reasonable to assume that it averaged out in most cases, and did not result in significantly skewed estimates.

Table App-1-3 shows the number of transects that were surveyed, by habitat type, in each of the five regions (see also Figure App-1-1). In many (though not all) cases where there appears to be poor NBC survey coverage for a given habitat-region combination, this was a result of few or no such habitat-region combinations existing. For instance, Mesquite-Catclaw habitat occurs only in southern Nevada, and is simply not present in the other four regions of the state.

Appendices

Figure App-1-1: Division of Nevada into regions for population estimates, and locations of NBC transects.

Appendices

Table App-1-3: Number of NBC transects surveyed by habitat and region, 2002-2009. Habitat types are those identified in the original GAP-based NBC stratification process.

Habitat Type	Region					
	Central	East	North	West	South	Total
Agricultural	2	0	0	1	5	8
Aspen	2	7	5	4	7	25
Coniferous Forest	0	2	3	14	4	23
Joshua Tree	1	0	0	0	20	21
Lowland Riparian	15	9	26	16	36	102
Mesquite-Catclaw	0	0	0	0	14	14
Mojave Scrub	0	0	0	0	22	22
Montane Riparian	6	35	34	13	9	97
Montane Sagebrush	3	2	4	2	3	14
Montane Shrub	3	4	2	0	5	14
Mountain Mahogany	1	4	4	0	0	9
Pinyon-Juniper	13	35	5	8	12	73
Sagebrush	20	6	4	3	26	59
Salt Desert	5	17	0	1	10	33
Wetland	6	22	1	1	2	32

The following formal sequence of steps was used to derive NBC-generated population estimates:

a) We determined the total number of hectares for each habitat type within each of the five regions based on the GAP map (Table App-1-4). Using this approach, 93% of the state's total land area could be classified as one of the NBC focal habitat types. The remainder consisted of cover types such as urban, barren, cliffs, alpine, etc. Thus this 7% of the state's total land area was excluded from the analysis
b) We calculated species-specific average density estimates (birds per 40 ha) for every NBC transect
c) We averaged the density estimates for all transects within a given habitat-region combination, and repeated this step for all other habitat-region combinations
d) We multiplied the overall density estimate for each habitat-region combination by the number of hectares of that habitat-region combination to produce a series of population size estimates for each habitat- region combination.
e) We summed all resulting population size estimates for a given species to produce a statewide population estimate

Appendices

Table App-1-4: Total area of land, in hectares, covered by each habitat type in each region of Nevada.

Habitat Type	Region				
	North	South	West	Central	East
Agriculture	191,253	18,060	59,157	149,950	97,400
Aspen	56,131	0	114	5,352	37,345
Coniferous Forest	8,840	29,393	59,990	1,760	126,442
Lowland Riparian	16,030	12,376	6,238	9,077	8,041
Mesquite-Catclaw	0	7,539	0	0	0
Mojave Scrub (combined with Joshua Tree)	0	2,878,464	0	65,941	123,822
Montane Riparian	1,186	0	556	4,242	2,389
Montane Shrubland	62,664	60,496	14,099	48,771	185,060
Mountain Mahogany	2,939	0	1,327	57,504	89,819
Montane Sagebrush	574,378	2	65,434	322,470	161,712
Pinyon-Juniper	59,300	115,978	228,094	984,092	1,484,705
Sagebrush	4,623,741	202,593	579,070	3,661,461	2,792,070
Salt Desert	1,730,663	473,072	107,785	3,211,603	1,244,730
Other (not used)	527,605	168,466	75,891	490,738	133,697
Wetland	1,768	318	2,826	69,884	31,396
TOTAL	7,856,496	3,966,756	1,200,584	9,082,845	6,518,627

Population size estimates were created for all priority passerine birds, hummingbirds, woodpeckers, doves, and easily-detected upland game birds and raptors. Although NBC methods were not designed specifically for raptors, NBC-derived population estimates for this species group corresponded fairly well with previous estimates, with some exceptions. Population size estimates for all species analyzed were rounded to the nearest round number within 5%. This was done to emphasize the imprecise nature of population size estimation, which differs from a total population count in that it includes error from extrapolation and sampling. We decided on a species by species basis whether or not the NBC population estimate was the best available estimate, as presented in the species accounts (see *Appendix 4* for a summary).

Other Population Size Estimates

Population estimates for many of this plan's Priority species could not reasonably be derived from either NBC or BBS data, particularly for waterfowl, waterbirds, shorebirds, and owls. Additionally, NBC-derived population estimates for some upland game birds and raptors were unreliable enough to merit consideration of other population size estimates. For these species groups, we relied on the key sources described previously to obtain population size estimates.

Because we chose only one population estimate to report on the front page of the species accounts, readers may wish to examine *Appendix 4*, where the comparison of all available estimates is summarized in tabular form. In the species accounts, we discuss the factors that might weigh in favor of one estimate or the other where appropriate.

Error Estimation for Population Size Estimates

It is generally understood that population estimates derived from any currently available data source are necessary very approximate. Methods of calculating population size estimates are continuing to be critically reviewed and recommendations being made (Thogmartin et al. 2006). The most important recommendation, of course, would be the collection of more and better monitoring data.

There are many sources of potential error in the process of generating a population size estimate, and integrating them meaningfully into a single error index is a very complex undertaking that deserves careful attention (e.g. Bart 2005b, Thogmartin 2010). Rather than reporting oversimplified (and possibly misleading) estimate errors, we chose to defer this exercise until a future revision of this plan.

Range Maps

For species range maps, we used actual detections of a species as the basis for creating known and presumed distributions within Nevada. This was a conservative, data-driven approach that contrasted, to some extent, with more typical approaches to range map creation. Detection records were obtained primarily from NBC data, the Nevada Breeding Bird Atlas project, the GBBO Aquatic Bird Count, and the NDOW diversity database (see "Sources of Information" section, above). For all of these sources, only records collected since the beginning of the Nevada Breeding bird atlas project (i.e. 1997) were used in order to avoid inadvertently plotting distributions that no longer apply. Other data sources, notably the *Nevada Upland Game Species Management Plan* (NDOW 2008) and personal observations from reliable experts, were occasionally used to supplement these sources, as noted in the species accounts. Once detections were mapped, the range maps were created using the following approaches.

For landbirds, we used the USGS basin and range shapefile to divide the state into a contiguous array of basins and mountain ranges. A bird sighting that occurred within a given basin or mountain range resulted in the extrapolation of "known distribution" to that entire basin or mountain range. For species present at intermediate elevations, detections often occurred in both basins and mountain ranges. Presumed ranges were then superimposed on known range by a subjective, iterative process involving opinion from several experts, outside map review, and biological context.

For waterbirds, waterfowl, shorebirds, and marshbirds, we used a similar approach employing the shapefiles that defined Open Water and Ephemeral Wetland and Playa habitats (see above), rather than basins and mountain ranges. A detection that occurred within or adjacent a water bodies was extrapolated throughout that water feature. Presumed range was then extrapolated to other water bodies, using a process similar to that described above for landbirds.

Despite our efforts to systematize the distribution mapping process, judgment calls were still required in many cases. It is important to note that the absence of a mapped "known" distribution for a species within a given part of the state is NOT intended to imply that the species is known to be absent from that area. Rather, it has not yet been observed, and definitive determination of presence or absence will require focused local survey efforts. We show both known and presumed range on most species maps to avoid this possible misinterpretation.

Threats Determination and Conservation Strategies

Assessment of conservation concerns and threats is primarily discussed in the *Conservation Concerns* chapter of this plan. Determinations as to whether or not conservation concerns represented threats to a given habitat or bird species were the result of integrating the Conservation Action Planning (CAP) outputs (TNC 2007), literature review, analysis, and substantial discussion among the Nevada PIF planning group. In presenting what we determined to be significant threats, we tended to focus on threats that may lead to significant negative changes in habitats or in the abundance / distribution of Priority species over the next ten years. We did not attempt to formally rank threats to a given bird or habitat; rather we presented only the threats that we regarded to be credible.

Likewise, conservation strategies were formed as the result of literature review, analysis, and feedback from the Nevada PIF planning group. Two PIF meetings were devoted entirely to developing group consensus on conservation strategies.

Appendices

Appendix 2: Nevada Bird List and Statuses.

Table App-2-1: Bird species that occur with some regularity in Nevada. Priority species under this plan are shown in **bold type**, with suffixes defined as follows: (C) = Conservation Priority species; (S) = Stewardship species; (SS) = Special Status species. Seasonal Status (in Nevada) is defined as follows:

Breeder = primarily present during the breeding season

Breeder/Migrant = both breeding populations and significant migrant populations that breed elsewhere occur in the state, and migrants are of conservation importance in areas where the species does not breed

Breeder/Winter = occurs in the state during all seasons, but not necessarily in the same areas

Migrant/Winter = non-breeding populations are most abundant and of greatest conservation interest (breeders are rare or absent relative to other seasons)

Extirpated = species historically nested in Nevada, but was extirpated in recent decades

Reintroduced = species historically nested in Nevada and was reintroduced after extirpation

Names and taxonomic order are in accordance with the AOU checklist through the 51st supplement (Chesser et al. 2010)

Common Name	Genus	Species	Seasonal Status
Greater White-fronted Goose	*Anser*	*albifrons*	Migrant
Snow Goose	*Chen*	*caerulescens*	Migrant/Winter
Ross's Goose	*Chen*	*rossii*	Migrant
Cackling Goose	*Branta*	*hutchinsii*	Migrant
Canada Goose	*Branta*	*canadensis*	Breeder/Winter
Trumpeter Swan (C)	***Cygnus***	***buccinator***	**Reintroduced**
Tundra Swan (C)	***Cygnus***	***columbianus***	**Migrant/Winter**
Wood Duck	*Aix*	*sponsa*	Breeder/Winter
Gadwall	*Anas*	*strepera*	Breeder/Winter
American Wigeon	*Anas*	*americana*	Breeder/Winter
Mallard	*Anas*	*platyrhynchos*	Breeder/Winter
Blue-winged Teal	*Anas*	*discors*	Breeder/Migrant
Cinnamon Teal (C)	***Anas***	***cyanoptera***	**Breeder/Migrant**
Northern Shoveler	*Anas*	*clypeata*	Breeder/Winter
Northern Pintail (C)	***Anas***	***acuta***	**Breeder/Migrant**

Appendix 3: Statistical Results

We gather here the statistical results for the NBC-based analyses summarized in the species accounts under the "Nevada-Specific Studies and Analyses" heading. For the priority songbirds in this plan that were sufficiently well sampled by the NBC, we conducted analyses of NBC data using GIS-derived transect attributes as explanatory variables. In general, we referred to this as "landscape-level" analysis. The statistical analyses are described in detail in *Appendix 1,* apart from the results which are reported below. In brief, the dependent variable was presence/absence of a given priority species. Most of the explanatory variables examined were proportional surface areas of each habitat type within each transect's effective sampling area (defined as the region lying within 200 m of at least one of the transect's ten point-count stations). Habitat types were those identified in the original GAP-based NBC stratification process, which varied slightly from the habitat types otherwise defined in this plan (see *Appendix 1*). One additional explanatory variable was:

> DISTANCE TO WATER: Shortest distance from any portion of the transect sampling area to the nearest year-round water source (with a maximum value of 10 km). Note that a positive relationship with distance would mean that the bird was more likely to occur farther from water.

We used logistic regression to analyze the relationships between bird presence (detection or non-detection) and habitat types or distance to water. The p-values of the univariate relationships are reported in the following tables:

Table App-3-1: Univariate p-values for habitat models of six Priority species in the **Great Basin** region. Significant positive relationships are in **Bold.** Positive relationships are denoted by "(+)" and negative relationships by "(-)".

Appendix 4: Comparison of Population Size Estimates for Priority Species in Nevada.

Because we report only one population size estimate on the front pages of the species accounts, here we gather all sources of estimates for comparison. One methodological issue should be noted. BBS-based estimates (Rich et al. 2004, and unpublished Blancher spreadsheet; see *Appendix 1: Methods*) are adjusted by several "correction factors" based on bird detectability. The most important is that raw count numbers are automatically doubled, under the assumption that only males are being detected. NBC estimates, in contrast, do not use correction factors, based on our indications that most of the more visible or local landbirds are being detected within the defined sample area of each survey point (see *Appendix 1: Methods*). Refinement of correction factors and determining when their use is appropriate are priority considerations for improving the population estimation process (Thogmartin et al. 2006).

Table App-4-1: Population size estimates for Priority species. NBC = Nevada Bird Count; BBS = Breeding Bird Survey, with analysis by Blancher (i.e. "Blancher spreadsheet"). Numbers in **bold** are the ones reported in the species accounts. "Source for reported estimate" gives citations or other source information about the estimate shown in bold. WAP = Wildlife Action Plan.

SPECIES	NBC	BBS	Other	Source for reported estimate

Appendix 5: Habitat Use of Conservation Priority, Stewardship, and Special Status Species.

Table App-5-1: The habitats used by Priority species, as listed in the individual species and habitat accounts. Habitat types are defined in *Appendix 1:Methods*. Dark grid cells indicate the habitat type(s) most commonly associated with a given species. Lighter gray grid cells indicate the habitat type(s) that are used less commonly, or seasonally. Species are listed in AOU taxonomic order.

Appendix 6: Priority Species Occurrence in Nevada Important Bird Areas

Many of the "Key Conservation Areas" listed in the species accounts are designated as Important Bird Areas under the Lahontan Audubon Society's Important Bird Area in Nevada Program (http://www.nevadaaudubon.org/iba.html). This program provides an excellent framework within which to organize bird conservation efforts, restoration projects, and activities involving public participation. The tables below summarize the seasonal occurrence of Priority species in all of Nevada's Important Bird Areas.

Table App-6-1: Confirmed and presumed occurrences of Priority species in Nevada's Important Bird Areas, **northwestern region**, with all historical records included. Species are listed in AOU taxonomic order. B = confirmed breeding; b = presumed breeding; M = confirmed migration (including winter); m = presumed migration (including winter); W = confirmed winter; w = presumed winter; N = confirmed non-breeding (excluding migration and winter); n = presumed non-breeding (excluding migration and winter).

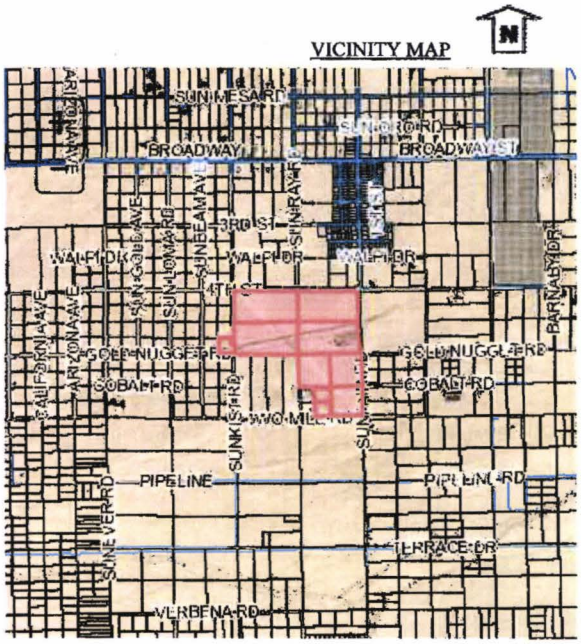
SAN BERNARDINO COUNTY
LAND USE SERVICES
PLANNING PROJECT NOTICE
15900 Smoke Tree Street, Hesperia, CA 92345

Referral Date:
February 17, 2015

ATTENTION REVIEWING AGENCIES

The development proposal listed below has been filed with County Planning. Please comment in the space below. You may attach additional pages as necessary.



Your comments must be received by Planning **no later than March 03, 2015 to be sure that they are included in the final project action.** Please refer to this project by the Applicant's name and the Assessor Parcel Number indicated below. If you have no comment, a reply is not necessary. If you have any questions regarding this proposal, please contact **Planner, TRACY CREASON** at **(760) 995-8143**, by email at **Tracy.Creason@lus.sbcounty.gov**, or mail your comments to the address above. If you wish, you may also FAX your comments to (760) 995-8167.

ASSESSOR PARCEL NUMBER:	**0607-231-11**	**(See map below for more information)**
PROJECT NUMBER:	**P201400482/CUP**	*** Multiple Parcel Associations ***
APPLICANT:	**MELIN, JESS/ NEXTERA ENERGY RESOURCES**	
LAND USE DISTRICT (ZONING):	**JT/IN**	
IN THE COMMUNITY OF:	**JOSHUA TREE/3RD/ SUPERVISORIAL DISTRICT**	
LOCATED AT:	**5500 SUNFAIR RD., JOSHUA TREE 92252**	
PROPOSAL:	**Conditional Use Permit to establish a 20 megawatt photovoltaic solar energy generating facility on 10 parcels totaling approximately 115 acres at the former Hi Desert (Roy Williams) Airport**	

If you want to be notified of the project decision, please print your name clearly and legibly on this form and mail it to the address above along with a self-addressed, stamped envelope. All decisions are subject to an appeal period of ten (10) calendar days after an action is taken.

San Bernardino County Government Center
385 N. Arrowhead Ave., San Bernardino, CA 92415-0182
15900 Smoke Tree Street, Hesperia, CA 92345
San Bernardino Office – (909) 387-8311 High Desert Office – (760) 995-8140
Fax (909) 387-3249 Fax (760) 995-8167

CONDITIONAL USE PERMIT
INFORMATION SHEET AND APPLICATION

Fees/Deposit:

LUSD Processing Fees			
Area Being Developed	0 to 0.99 acres	1 to 4.99 acres	5 acres and over
Actual Cost Initial Deposit (J631)	**$6,705.00**	**$7,450.00**	**$8,940.00**

Please Note: This is a deposit only. The basic review fees for this application are charged on an "actual cost" basis. Your project will be charged at the hourly and mileage rate(s) as provided in County Code Section 16.0228B(b) ($65 to $250/hr) as well as any other costs incurred by the County in processing your project. These costs include, but are not limited to, any required advertising, mailings, and notices. Other divisions and departments will be charging to the deposit listed above. You are responsible for all charges made to the project account. If account funds are depleted an additional deposit will be required. If an additional deposit is required it must be paid to allow staff to continue processing. Any failure to pay the required deposit will result in suspension and possible termination of the project review process as well as sending your account to collections. After the review is completed, a minimum deposit balance will be required for condition compliance processing. For more information on fees, please contact County Planning.

In addition to the deposit listed above other fees may be required for reviews by County Fire, Environmental Health Services, Code Enforcement, Surveyor, Public Works and special report reviews by Building and Safety. State Fish and Game fees as noted on the attached pages may be required before your project can be approved.

A Conditional Use Permit (CUP) is required by the County Development Code to evaluate the location, design and operation for certain new or expanded land uses as specified in each Land Use District. These uses, although generally deemed to be consistent with the purpose and intent of the Land Use District, typically have characteristics which require special consideration in order to avoid conflicts with surrounding land uses. **Note: Wireless telecommunication facilities are required to be submitted on a specialized application.**

The Conditional Use Permit application and process provides the County the opportunity to completely review the proposed project before its implementation. Conditions of Approval will be required of the project prior to its final approval or implementation.

Conditional Use Permits will be reviewed by Planning Staff and will be considered by the Planning Commission at a public hearing. Actions of the Planning Commission may be appealed to the Board of Supervisors within ten days following the date of the action. Appeals must be made by means of a separate application and may require an additional fee.

Please use this information sheet as a checklist to assemble the materials required for the submittal of your Conditional Use Permit and bring it with you when you submit your application. An appointment is not required to submit your application; however, appointments are available upon request. If you wish to schedule an appointment, please call one of the numbers listed above.

GENERAL PROCEDURES

1. Submit application and fees – County staff will use the checklist to determine whether your application may be accepted. The County's standard Land Use Application shall be used and is contained in this packet.
2. Determination of Application Completeness – County staff will determine whether the materials you have submitted are adequate or if additional materials or reports are required. You will be notified in writing if any additional materials are required.
3. Environmental Action Determination – County staff will prepare an Environmental Initial Study in compliance with the California Environmental Quality Act (CEQA). It is through the Initial Study that the determination is made as to what type of environmental determination will be required. If an Environmental Impact Report (EIR) is required, staff will contact you to explain the process and the costs.
4. Application processing – The project planner will have the project and materials reviewed by all appropriate County Departments and Agencies. Any required corrections, questions or revisions to the plans or other materials will be reviewed by the project planner and then provided to you.
5. Recommendations, conditions of approval and final report – The project planner will prepare these materials for consideration by the Planning Commission.

CHECKLIST OF SUBMITTAL MATERIALS

Please use this checklist as you assemble the materials for the submittal of your application. County staff will use the checklist to determine whether your application is acceptable for submission. **If your submittal package does not contain all of the information listed below, your application will not be taken in and receipted for processing.** If you have any questions about the items requested or if you wish to obtain information on processing schedules, please call the Customer Service Unit at (909) 387-8311 or (760) 995-8140.

Section A – Fees/Deposit

1. X Check or money order made payable to "San Bernardino County" in the correct amount.

LUSD Processing Fees			
Area Being Developed	0 to 0.99 acres	1 to 4.99 acres	5 acres and over
Actual Cost Initial Deposit (J631)	**$6,705.00**	**$7,450.00**	**$8,940.00**

Provide **one copy** of the following receipts or a letter stating such fees are not applicable:

2. X **Receipt** from the Environmental Health Services Division (DEHS) of payment of required review fees. Contact DEHS at (909) 387-4666 for fee amount, applicability and payment prior to application submittal
3. X **Receipt** from the appropriate fire jurisdiction of payment of required review fees.
4. X **Receipt** from the Department of Public Works/Land Development Division of payment of required review fees.

Note: If your project is within a Geologic Hazard Overlay District, you will be required to pay the Building and Safety Division the review fees for any required geologic reports. You will be notified when you will need to complete this part of the process. The fee amount will be as established by the County Fee Ordinance.

The fees listed above (2 - 4) for DEHS, County Fire, Public Works and Building and Safety are in addition to the "actual cost" deposit. Additional fees will be required if the application is the subject of a Code Enforcement action.

"Actual Cost Initial Deposit" – ***This is a deposit only. The basic review fees for this application are charged on an "actual cost" basis. Your project will be charged at the hourly and mileage rate(s) as provided in County Code Section 16.0228B(b) ($65 to $250/hr) as well as any other costs incurred by the County in processing your project. These costs include, but are not limited to, any required advertising, mailings, and notices. Other divisions and departments will be charging to the deposit listed above. You are responsible for all charges made to the project account. If account funds are depleted an additional deposit will be required. If an additional deposit is required it must be paid to allow staff to continue processing. Any failure to pay the***

required deposit will result in suspension and possible termination of the project review process as well as sending your account to collections. After the review is completed, a minimum deposit balance will be required for condition compliance processing. For more information on fees, please contact County Planning.

In addition to the deposit listed above other fees may be required for reviews by County Fire, Environmental Health Services, Code Enforcement, Surveyor, Public Works and special report reviews by Building and Safety. State Fish and Game fees as noted on the attached pages may be required before your project can be approved.

Section B - County Documents

5. X — **Two copies** of a completed Land Use Application Questionnaire.
Only two copies of the application are required for the initial filing of this application. *Revisions may or may not be required. When Customer Service Unit staff determines that the application is complete, you will be required to submit additional copies of the application. The specific number of copies to be submitted will be determined at that time.*
6. X — **One copy** of the completed Hazardous Waste Site Certification form contained in this packet.
7. X — **Two copies** of the Adequate Service Certification for water and sewer service. Please use the forms (A, W1, W2, S1 and S2) at the end of this packet.

Section C – Other Documents

8. X — **Two copies** of a plot plan drawn at a scale to accurately delineate the proposed project as it is to be constructed. A conceptual plan is not acceptable. (Folded accordion style - 8" x 10 1/2" size.) (Refer to the Plot Plan Checklist for specific requirements.) *Only two copies of the plot plan are required for the initial filing of this application. Revisions may or may not be required. When Customer Service Unit staff determines that the plan is complete, you will be required to submit additional copies of the plot plan. The specific number of copies to be submitted will be determined at that time.*
9. X — **One copy** of the plot plan reduced to 11" X 17".
10. X — **One copy** of a "Letter of Intent" which specifically details the proposed business or operation. Include hours of operation, number of employees, truck trips, and any other details that will accurately describe the business.
11. X — **One copy** of a) the recorded Grant Deed or b) the Quit Claim Deed with the previous Grant Deed for each lot or parcel or c) a copy of a current Preliminary Title Report (issued within 60 days of filing).
12. X — **One certified copy** each, if applicable, of the Articles of Incorporation including the latest statement of officers; the Partnership Papers (limited or general); or the recorded Fictitious Business Name Statement naming the owner(s) of the firm, if either the Grantor or Grantee are Corporations, Partnerships, or Fictitious Firms
13. X — **One copy** of the trust agreement if a trustee is listed as the property owner.
14. X — **One copy** of the appropriate Assessor's map. This may be obtained from the Assessor's Office.
15. X — **One copy** of the United States Geological Survey (USGS) Map of the project area clearly showing project boundaries and labeled with the quadrangle map name and applicant's name. A legible photocopy is acceptable. The USGS map may be purchased at a local blueprint company.
16. N/A — **One copy** of any letter or document received from the County or other agency regarding this project.
17. X — **One copy** of original color photos of the project site from various angles (digital photos on a disk/CD are preferred). Include a vicinity map indicating the location and direction of view.
18. X — **Two copies** of a Water Quality Management Plan (WQMP) with a cover page that contains contact information for the project applicant and engineer. Detention basins shall be designed to closely conform to the natural topography. Native, drought-tolerant landscaping shall be required to maintain the natural aesthetic.

Section D - Special Studies (if applicable)

19. N/A — **Three copies** of a Geologic Feasibility Study for any property in a Geologic Hazard (GH) Overlay District.
20. N/A — **Four copies** of a Slope Analysis for any project in a Fire Safety Review Area (FS) Overlay District where grading is proposed.
21. X — **Three copies** of any other studies prepared for this project.
22. X — **Four copies** of any required traffic study. A **traffic study** can be required. A final determination will be made after submittal of the project.

23. X **Five copies** of any required Endangered Species Report and/or general Biological Study (Desert Tortoise, Mojave Ground Squirrel, Southern Rubber Boa, Delhi Sand Loving Fly, etc.).
24. N/A **Two copies** of the Fiscal Impact Report for any mobilehome or multi-family project of 50 units or more.
25. N/A **Four copies** of a Water Supply Assessment in accordance with SB 221 and SB 610 for a residential project of 500 units or more; shopping centers or business establishments employing more than 1,000 people or 250,000 SF of floor space; hotels more than 500 rooms; industrial uses on 40 acres and greater, or 650,000 SF or more.

Section E – Public Notice Materials/Surrounding Property Owners Certification
Please refer to the sheet titled "Surrounding Property Owners Certification" for details regarding requirements and label format. This sheet also includes the required signature block for the person who prepared the information and labels. ***The Mailing Labels should include the applicants' and representatives' mailing addresses.***

26. X **Two** adhesive sets *and* one reproducible copy of **mailing labels** for all property owners that own property within the following specified areas. The following are based on the project area being:
    ____ 20.0 acres or less: All parcels within 300 feet of the external boundaries of the project parcel.
    X 20.1 acres to 160 acres: All parcels within 700 feet of external boundaries of the project parcel.
    ____ 160.1 acres or greater: All parcels within 1,300 feet of the external boundaries of the project parcel.
27. X **One copy** of the certification sheet signed by the person who prepared the list and labels.
28. X **One copy** of a radius map showing all the Assessor's Parcels at the same scale and including the radius notification specified above based on parcel size.

Section F – Additional Materials*
Technical studies for traffic, drainage, noise, air quality, biotic resources, archeological resources, groundwater resources, hazardous materials, visual impact or other issues may be required to process your application. You will be notified if any additional materials will be required for the application.

Section G – Redevelopment Area: If a project is in a Redevelopment Area, building colors, signage, and landscape plans should be provided.

Section H – Plot Plan and Building Elevations: Use the following checklist to be sure that your plans include all of the required elements. The plot plan is a drawing, to scale, on one sheet of paper (minimum size of 18" x 24") of the entire land parcel showing buildings, improvements, other physical features and all dimensions. Building elevations must be fully dimensioned and illustrate proposed structure(s) from all sides; the building drawings should also show each story of any multi-story building. Remember that the staff and Planning Commission are not familiar with the property and will need this information to evaluate your project. **If the plans are not legible or do not contain the information listed below, your application will be returned.**

1. X Official Stamp Area: A 4 inch by 14 inch area in the upper right hand side of the plot plan shall be left blank and labeled "Official Use Only".

2. X Plan Identification: The lower right hand corner of the plan shall contain the following information in this order: a) Assessor's Parcel Number(s) (APN:); b) application type *and proposed land use/building size "CUP for ____" c) the names, addresses and telephone numbers of the applicant, representative, recorded Property Owner(s) (if different from applicant), and plan preparer and d) plot plan preparation date and any revision date(s).*

3. X Utilities: Indicate names, address and telephone numbers of water company, sewage disposal, electric, gas, telephone, cable television. If no utility company, indicate method of supply.

4. X Legal Description: Complete legal description of the property including number of acres. Include APN. If a portion of a large parcel is being developed, include a detailed description of that portion.

5. X North Arrow: Indicate north (pointing to top or left hand side of the plan), date of drawing and the scale. Use an Engineer's Scale (1" to 10', 1" to 20', etc.)

6. X Dimensions: Show all property lines and dimensions. Also, show boundary lines of project with dimensions if only a portion of the property is being developed. *Property lines shall be shown as a solid, distinctive line. Entire property must be shown.*

7. X Roads/Easements: Indicate location, names, centerline, existing and proposed widths of boundary streets, and recorded road, utility, and drainage easements on the property. If none exist, indicate by a note that no easements exist. If property is not on a road or easement, show legal and physical access to property.

8. X Paving: Delineate edge of paving (if any) and indicate any existing curbs, driveways, and sidewalks. If no paving exists, indicate type of road (dirt, or gravel) and a note that curb and gutter and/or sidewalks do not exist. If paving does not exist, provide in a notation the distance to nearest paved road and name of road.

9. X Drainage: Indicate any drainage or hilly terrain by flow-line arrows and contour lines. Show proposed drainage of site by flow-line arrows and swales.

10. X Grading/Topographic Information:
_____ Show existing contours and proposed finish contours.
_____ Show finish elevations at lot corners and graded areas.
_____ Show finish grades for all structures, pads and parking surfaces.
_____ If no grading is proposed, state " No grading proposed."
_____ Show location, size and height of any existing or proposed walls.

11. X Land Use District: Indicate existing and proposed General Plan Land Use District (zoning) for project and all adjacent property including across any streets. If adjacent property is within a City, list the City and City Zoning.

12. X Structures/Land Use (Adjacent Areas): Indicate the existing land use, including "Vacant" or "citrus grove," of structures on all adjacent property including areas across any adjacent streets. Indicate distance to any structure that is within 20 feet of the project property line.

13. X Structures (Project Area): Indicate with dimensions all existing and proposed structures, including but not limited to power poles, towers, fences, trash enclosures, signs, septic systems. Indicate type of construction and approximate age of any existing/proposed structures.
_____ Locate by distance in relation to other structures and property lines.
_____ Indicate existing structures that are to remain or to be removed.
_____ Indicate the specific use of all existing and proposed structures.
_____ Indicate height, building footprint dimensions, including eave overhang projections, square footage of each story and number of stories including basements.
_____ Show location and height of any wall.

14. X Vicinity Map: Indicate project location within a general vicinity map with a north arrow. Indicate nearest cross streets, major access roads and community name.

15. X Signage: Provide a dimensioned side elevation of any proposed free-standing or monument identification sign including the proposed "copy" (wording). Include distance from both top and bottom of sign to grade. Refer to Development Code for information on allowable type and size of signs. If no sign is proposed state "No signs proposed". If a sign is proposed at a later date, additional review and costs may be incurred.

16. X Parking: [Refer to the County Development Code for details.] Show all parking areas with dimensions, number/type of spaces, and surfacing materials. Show the formula per the San Bernardino County Development Code by which you computed the number of spaces required for each use/tenant/unit. Indicate the number of spaces required for each use and indicate the number of spaces proposed as well as the minimum number of spaces required. Use the following chart as an example:

PARKING SPACE ANALYSIS:

Land Use/Requirement	Parking Rate	Bldg. Size/rate	Required	Provided
Warehouse	1/1000 sq. ft.	10,000 sq.ft. ÷ 1000 sq.ft.	= 10 minimum	12
Office/retail	1/250 sq. ft. (minimum 4)	600 sq.ft. ÷ 250 sq.ft/min. 4	= 4 minimum	4
restaurant	1/3seats (minimum 10)	1000 sq. ft. w/20 seats/min 10	= 10 minimum	12
Loading Zone	1/5000 per use	11,600 sq. ft.	= 3 minimum	3
TOTAL		**11, 600 sq.ft.**	**27**	**31**
Van accessible spaces for the disabled			1	2
Disabled person spaces			1	0

17. N/A Path of Travel: Show a marked path of travel from handicap space(s) and from the street to the main building(s).

18. X Lot Coverage: Show percentages of parcel covered by impervious surface, landscaping, and open space.

19. X Plant and Tree Protection: If no protected or endangered trees exist on the site state "No Protected Plants", otherwise show the location, size, and type of all native trees, including unbranched cacti, yuccas, palms and joshuas, and indicate whether any of the following trees are to be removed:

    Valley or Mountain Areas – Six inches or greater in diameter or 19 inches in circumference measured at 4.5 feet above average ground level of the base.
    Desert Areas – All Joshua trees and all species of century plants, nolinas and yuccas. Creosote rings that are 10 feet or greater in diameter. For smoketrees and mesquites, two (2) inches or greater in diameter or six (6) feet or greater in height. All plants protected by the State Desert Native Plants Act shall be protected in accordance with that ordinance.

20. X Landscaping: Show areas to be landscaped. If in a ReDevelopment Area (RDA), a project specific landscaping plan is required at time of submittal.

21. X Lighting: Show location of outdoor lighting. In a note, indicate the type of lighting and planned shielding design.

22. N/A Commercial, Industrial, or Institutional Projects: Show uses of all buildings and structures with number of occupants, hours of operation, etc. If proposed use is storage, indicate type of material to be stored.

23. X Truck traffic: If truck activity is involved in the project, show the turn maneuvers for the driveways relative to the street.

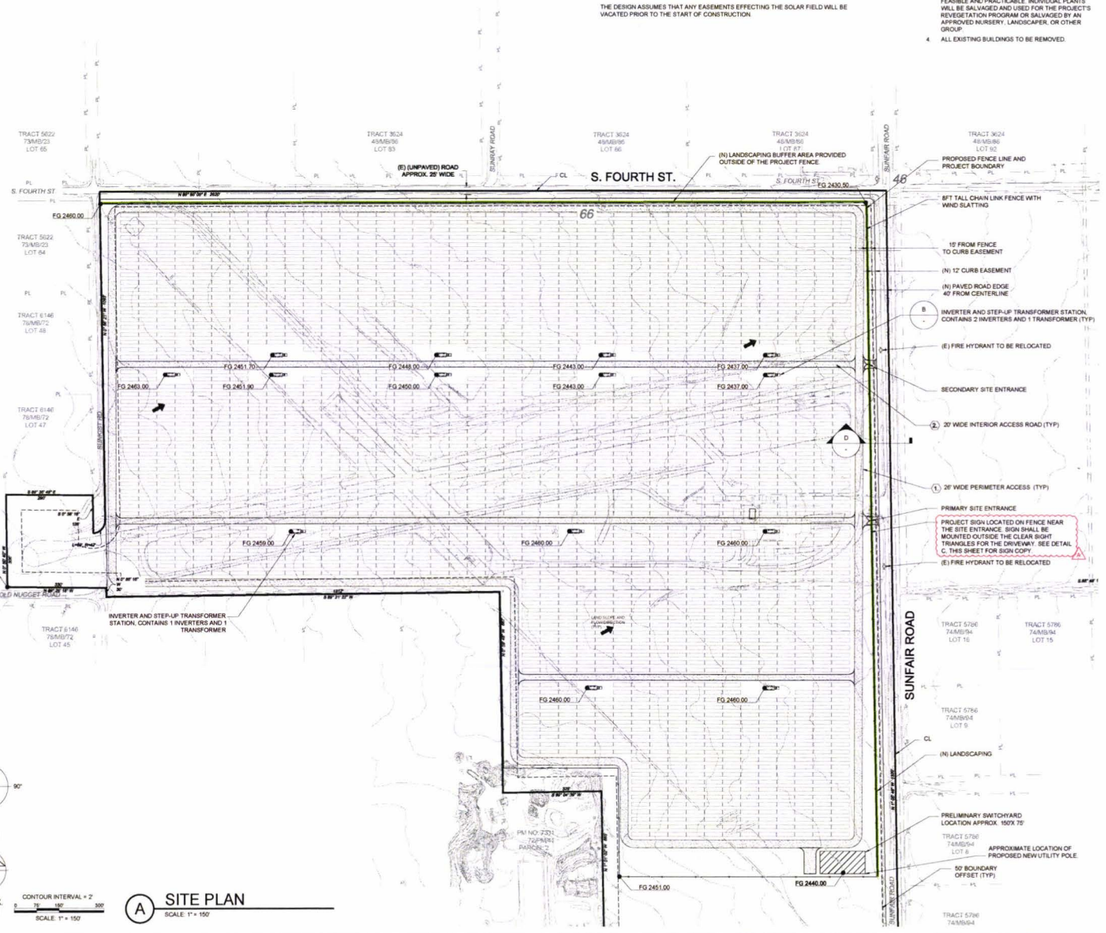
16. CC&R'S PER 5236/OR/439. BUILDING RESTRICTIONS (DOCUMENT STATES THAT THE PLANNING COMMISSION CAN RE-ZONE)
17. ELECTRIC POWER EASEMENT PER 6271/OR/415
18. PUBLIC ROAD EASEMENT PER 1966-0283419

OTHER ITEMS LISTED WHICH AFFECT ALL PARCELS: ANY EASEMENTS NOT DISCLOSED BY PUBLIC RECORDS; MATTERS WHICH MAY BE DISCLOSED BY AN ALTA/ACSM SURVEY; RIGHTS OF PARTIES IN POSSESSION. REFER TO P.T.R.

THE DESIGN ASSUMES THAT ANY EASEMENTS EFFECTING THE SOLAR FIELD WILL BE VACATED PRIOR TO THE START OF CONSTRUCTION.

KEYED NOTES:

1. PERIMETER ACCESS: 26' WIDE CLEAR ACCESS WAY TO BE CONSTRUCTED USING APPROVED NATIVE MATERIAL OR GRAVEL, COMPACTED TO 85% COMPACTION.
2. INTERIOR ACCESS: 20' WIDE CLEAR ACCESS WAY TO BE CONSTRUCTED USING APPROVED NATIVE MATERIAL OR GRAVEL, COMPACTED TO 85% COMPACTION.



NOTES:

1. SAFETY LIGHTING WILL BE INSTALLED AT THE ENTRY GATES AND THE SWITCHGEAR LOCATION. A LIMITED AMOUNT OF LIGHTING WILL BE INSTALLED AND WILL BE DESIGNED TO PREVENT SPILLOVER INTO NEIGHBORING PROPERTIES. THERE WILL BE OPERABLE LIGHTING AT EACH CONVERSION STATION, BUT THESE UNITS WILL BE USED AS NEEDED AND WILL NOT TYPICALLY OPERATE AT NIGHT. THE ENTRY WILL HAVE FIXTURES TO PROVIDE MINIMAL LIGHTING AND WILL HAVE ADDITIONAL ON-DEMAND (E.G. TIMER) LIGHTING AS NEEDED OR REQUIRED.
2. GRUBBING AND GRADING ACTIVITIES WILL BE LIMITED DUE TO THE PREVIOUS DEVELOPMENT ACTIVITIES AND INHERENTLY SPARSE VEGETATION. SITE GRADING WILL BE SOLELY FOR STORM WATER CONTROL. THE PREVIOUS DEVELOPMENT SIGNIFICANTLY REDUCES THE NEED FOR SITE LEVELING, CUT AND FILL, AND OTHER INVASIVE SITE MODIFICATIONS. FOR THE VAST MAJORITY OF THE ARRAY AREA, NO SITE GRADING WILL BE EMPLOYED.
3. PLANT AND TREE PROTECTION: SPECIES IN THE JOSHUA TREE SOLAR PROJECT VICINITY THAT ARE SUBJECT TO PERMITTING INCLUDE JOSHUA TREE (*YUCCA BREVIFOLIA*) AND SEVERAL SPECIES OF CACTI (SILVER CHOLLA, BUCKHORN CHOLLA [*CYLINDROPUNTIA ACANTHOCARPA*] PENCIL CHOLLA [*C. RAMOSISSIMA*] AND BEAVERTAIL CACTUS [*OPUNTIA BASILARIS*]). PLEASE SEE *DESERT TORTOISE SURVEY AND GENERAL BIOLOGICAL RESOURCES ASSESSMENT FOR THE JOSHUA TREE SOLAR FARM (AIRPORT SITE) SAN BERNARDINO COUNTY, CA, 2012. TETRA TECH* FOR THE LOCATIONS OF THESE PLANTS. WHERE FEASIBLE AND PRACTICABLE, INDIVIDUAL PLANTS WILL BE SALVAGED AND USED FOR THE PROJECT'S REVEGETATION PROGRAM OR SALVAGED BY AN APPROVED NURSERY, LANDSCAPER, OR OTHER GROUP.
4. ALL EXISTING BUILDINGS TO BE REMOVED.

Letter Of Intent

Joshua Tree Solar Farm

1.0 INTRODUCTION

Joshua Tree Solar Farm, LLC (JTSF or applicant) is pleased to submit this Conditional Use Permit (CUP) application package for the Joshua Tree Solar Farm project (the "project"). JTSF proposes to construct, own, and operate a 20 megawatt (MW) alternating current (AC) solar photovoltaic (PV) generating facility located on approximately 115 acres of disturbed land, 3.5 miles east of the city of Joshua Tree and 1.3 miles north of Twentynine Palms Highway in unincorporated San Bernardino County. The generated power will be delivered to the electrical grid via a 33 kilovolt (kV) interconnection to the Southern California Edison (SCE) distribution system.

The project location has been deliberately chosen to repurpose a previously developed site, the deactivated, privately owned Hi Desert (or Roy Williams) Airport (airport). JTSF understands and respects the principles of avoiding, minimizing and mitigating when proposing or building a renewable energy project. The siting of this project was done with thought and careful planning.

Initially, a larger parcel of vacant land (approximately 160 acres) to the south of the airport was being considered for the project. Concerns about surface hydrology and undisturbed desert vegetation led JTSF to evaluate a project site to the north, when it became known that the deactivated airport was available for sale. Land option agreements were made with the owner of the airport and environmental studies of the airport site commenced. It was soon determined that the 115 acres constituting the airport site were not sufficient in quantity to produce 20 MW_{AC} of power using a tracking PV system.

JTSF then began negotiations to purchase an additional 40 acres adjacent to the airport to the east. Again, environmental studies including cultural resources, biology, and waters of the State were conducted to assess the environmental and existing condition of the 40 acres. After hearing community concerns about the use of undisturbed desert land for solar project, JTSF decided to revert back to only using the 115 acres on the disturbed airport site. By doing so, and in order to still meet the objective of producing 20 MW_{AC} of power, the configuration was changed from tracking to fixed tilt. A fixed tilt layout is able to accommodate more PV panels in a smaller space.

The following factors contributed to the decisions in the site selection:

- The project site is a deactivated airport which has already been disturbed. Development of this site would lower the environmental impact to vegetation and wildlife habitat as compared to developing on undisturbed land.
- The land is fairly level, reducing the need for grading.
- There is existing access to the site off of Twentynine Palms Highway and Sunfair Road., eliminating the need for new roads or new right of way.
- The project site is in an area with an excellent solar energy resource with high irradiance and is of sufficient size to produce up to 20 MW_{AC} of electricity from PV solar panels.

AR063244

- The project site is adjacent to an existing SCE electrical distribution line which will take energy produced by the project into the grid. Only minimal upgrades to the existing line will be required.

Therefore, in siting this project, JTSF has **avoided** impacting undisturbed desert habitat, **minimized** the footprint and other environmental concerns, and is prepared to **mitigate** any residual minor impacts of the project.

1.1 PROJECT OBJECTIVES

The primary objective of the project is to assist in achieving or exceeding the State's Renewable Portfolio Standards and greenhouse gas emissions reduction objectives by developing and constructing California Renewable Portfolio Standards-qualified solar generation, approved under Senate Bill X12, which established renewable energy targets of 20 percent total electricity sold to retail customers by the end of 2013, 25 percent by the end of 2016, and 33 percent of total electricity sold to retail customers by 2020.

The project specific objectives are as follows:

1. Develop approximately 20 MW_{AC} of renewable solar energy that that can operate during on-peak power periods, indirectly reduce the need to emit greenhouse gases caused by the generation of similar quantities of electricity from either existing or future non-renewable sources to meet existing and future electricity demands.
2. Develop approximately 20 MW_{AC} of renewable solar energy that satisfies the terms of the Project's Interconnection Agreement, while minimizing environmental impacts by using previously disturbed land.
3. Develop a renewable project that is consistent with the principles contained in the draft Desert Renewable Energy Conservation Plan (DRECP 2014), the County of San Bernardino General Plan (San Bernardino 2014a), and the draft Solar Ordinance developed by San Bernardino County (San Bernardino 2014b). See Attachment A of this Letter of Intent.
4. Invest approximately 50 million dollars in total expenditures, which will help to support the economy in San Bernardino County through the creation of jobs and capital expenditures.
5. Maximize the potential for creation of local construction jobs for a variety of trades, thereby supporting unemployment reduction goals in the area for the duration of construction.

2.0 PROJECT DESCRIPTION

The following sections provide further detail on the design, construction, operation, maintenance, and decommissioning of the project. Preliminary design is underway, with project size, typical equipment, and array configurations determined. A final selection of solar modules, inverters, mounting system, and precise dimensions will be decided during detailed design and equipment procurement. A project overview is provided in Table 1 below. Specifics of the project are detailed in the following subsections.

AR063245

Table 1: Project Summary Information

Site Capacity	20.0 MW_{AC}
Collection and Intertie	33 kV line (SCE)
Array Configuration	Fixed tilt 15-25 degrees

The following project plans will satisfy County guidelines on project development, design, construction, and operation of the project:

- The effective service life of the project is approximately 30 years (before major overhaul of equipment) with the potential to repower
- Site grading will be minimal due to previous development and flat terrain
- Grading and cut/fill operations are expected to be limited to storm water management
- Recycling goals of 50 percent will be implemented where possible of all building materials and packaging
- Existing reusable structures will be disassembled and materials recycled as possible (hangars, shelters, etc.)
- Where practical, site asphalt pavement will remain; concrete pads will be demolished and removed
- Site debris that cannot be reused or recycled will be taken to an off-site disposal facility approved for disposal of the target debris

2.1 LOCATION AND EXISTING CONDITIONS

The 115-acre Joshua Tree project site is within Section 21, Township 1 North, Range 7 East, as mapped on the United States Geological Survey 7.5-minute series Joshua Tree North, California, and Sunfair, California quadrangles (Figure 1).

AR063246

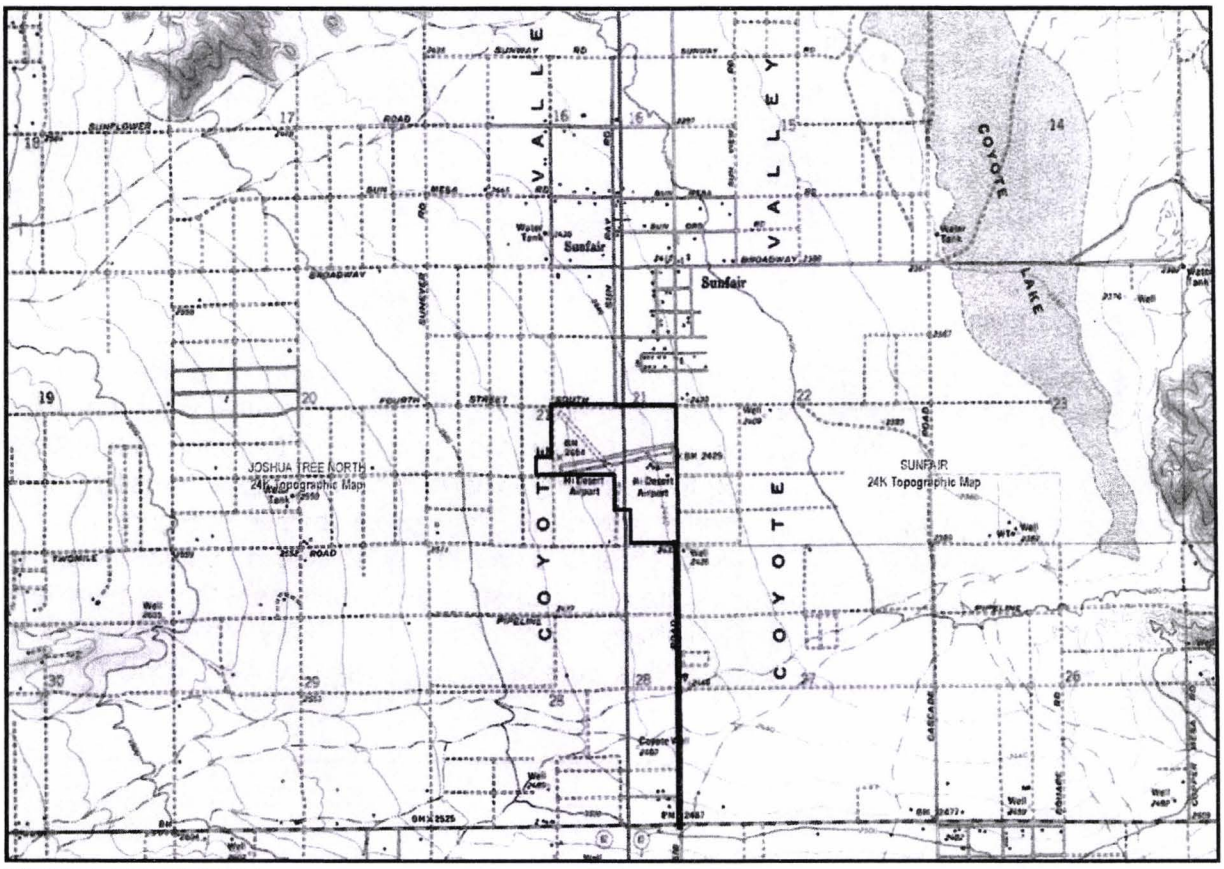

FIGURE 1: PROJECT SITE

The topography of the project site is relatively flat and ranges in elevation from approximately 2,470 feet above mean sea level on the western boundary of the site to 2,430 feet above mean sea level on the northeast corner of the site. The project site is previously developed and is accessed through Sunfair Road, a paved County road that runs along the eastern border of the site. The project site is bordered by Two Mile Road to the south, unpaved Fourth Street to the north, and unmaintained vacant land to the south and west. Hi-Grade Materials Company occupies the parcel adjacent to the southwest border of the project site. The current composition of the existing land is best described as vacant land of dirt and sand with a sparse vegetative community consisting of native grasses and shrubs. A summary of the Assessor's Parcel Number designations for the site are summarized in Table 2.

Table 2: Assessor's Parcel Number Index and Parcel Areas

Parcel Number	Acres
0607-231-12-0-000	20.00
0607-231-13-0-000	19.24
0607-231-14-0-000	20.00
0607-231-11-0-000	19.24
0607-231-09-0-000	10.00
0607-231-07-0-000	10.00
0607-231-15-0-000	2.50
0607-231-18-0-000	2.50

AR063247

Table 2: Assessor's Parcel Number Index and Parcel Areas

Parcel Number	Acres
0607-231-10-0-000	9.39
0607-364-06-0-000	2.14
Total	**115.01**

2.2 PROJECT LIMITS

The project footprint is defined by the property boundaries of the airport. The site-produced electrical energy will be collected and routed to the switchgear adjacent to the entry gate. The combined output of the plant will be routed from the switchgear through underground conductors to the southeast corner of the property where the conductors transition from underground to overhead and interconnect with SCE (grey circle, below in Figure 2). The distribution line, provided by SCE, runs due south along the west side of Sunfair Road on existing or to-be-replaced distribution structures in an existing utility easement to the main tie-in on the south side of Twentynine Palms Highway (also referred to as Hwy 62). The upgraded distribution line will be on SCE property and is outside the property boundary containing the solar arrays.

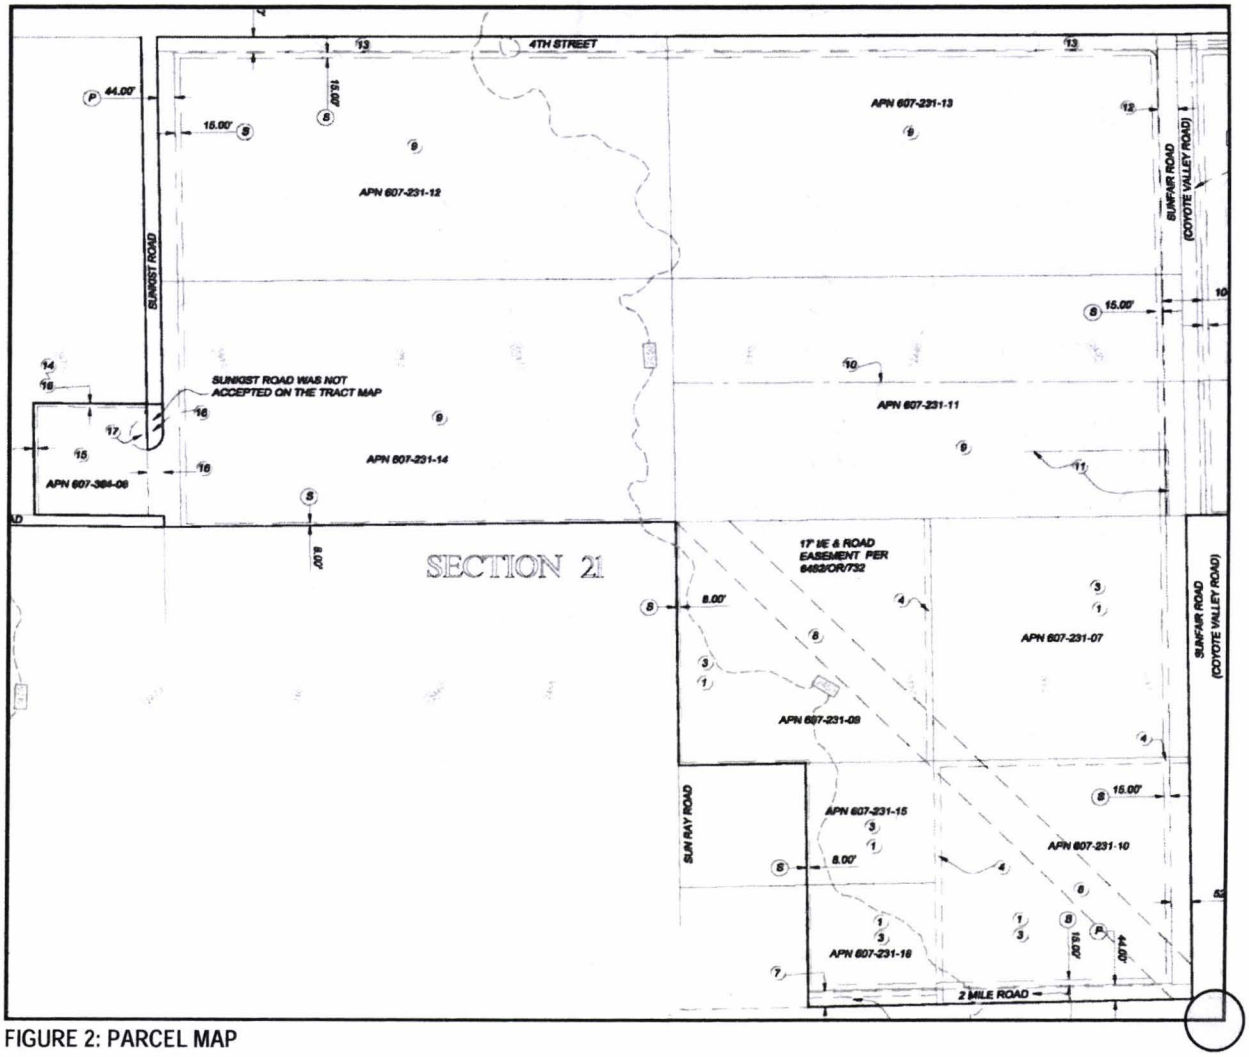

FIGURE 2: PARCEL MAP

AR063248

2.3 FACILITIES OVERVIEW

The overall project will have a maximum capacity of 20 MW_{AC} using fixed tilt configuration. The preliminary Site Plan is shown below as Figure 3.

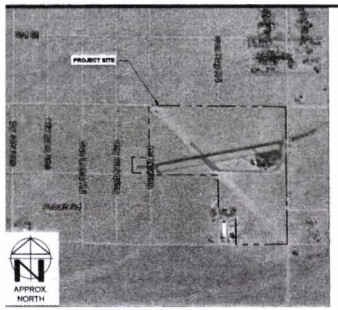
The project employs solar PV modules for energy generation, power conversion stations, and typical electrical equipment to collect the produced energy and deliver it to the point of interconnection with SCE's distribution system. The PV modules produce low-voltage Direct Current (DC) electrical power which is collected and delivered to the utility-scale inverter stations distributed throughout the site. The power conversion stations convert DC electricity to AC electricity and step it up to medium voltage of 33 kV. The power is collected at medium voltage, fed through the appropriate protective equipment, and delivered to the utility at the point of interconnection.

2.4 MODULES

The PV modules convert incoming sunlight to DC electrical energy. Modules are arranged in series to effectively increase output voltage. These series chains of modules are called "strings" in industry terms. The "string" is the basic building block of power conversion in the solar array. The chosen PV technology type will either be crystalline silicon or thin film (copper indium gallium selenide or cadmium telluride).

2.5 ARRAY MOUNTING SYSTEM

The modules will be mounted on a steel and aluminum structural system ("racking" system) which will be supported, when practical, by driven piers (piles) directly embedded in the ground. The front (south, lower) side of the arrays with fixed tilt racking will maintain a 24-inch clearance from ground level. The array height will generally be approximately 7 feet from ground level. The highest maximum height of an array (from the ground to the north, upper side) will be approximately 10 feet, or less than the height of the inverters.



2.6 POWER INVERTER STATIONS

The Inverter Stations convert the DC electrical energy from the PV arrays into AC. These stations perform three critical functions for the plant: (1) collect DC power in a central location, (2) convert the DC power into AC power, and, (3) convert low-voltage AC power to medium-voltage AC power at the appropriate grid potential.

Each inverter station consists of DC collection equipment (junction boxes and overcurrent protective devices, etc.), utility-scale inverters, and a low-to-medium-voltage transformer. The output power from the inverter stations is then fed to the AC collection system, an underground network of medium-voltage conductors and collection switchgear, discussed next. While the preliminary design is based on 750 kW_{AC} utility-scale inverters and 1.6 MVA (megavolt amps) transformers (Figure 4), the final rating will be determined during detailed design and equipment procurement. The typical height of an inverter station is approximately 9 feet, with a maximum possible height of approximately 10.5 feet.

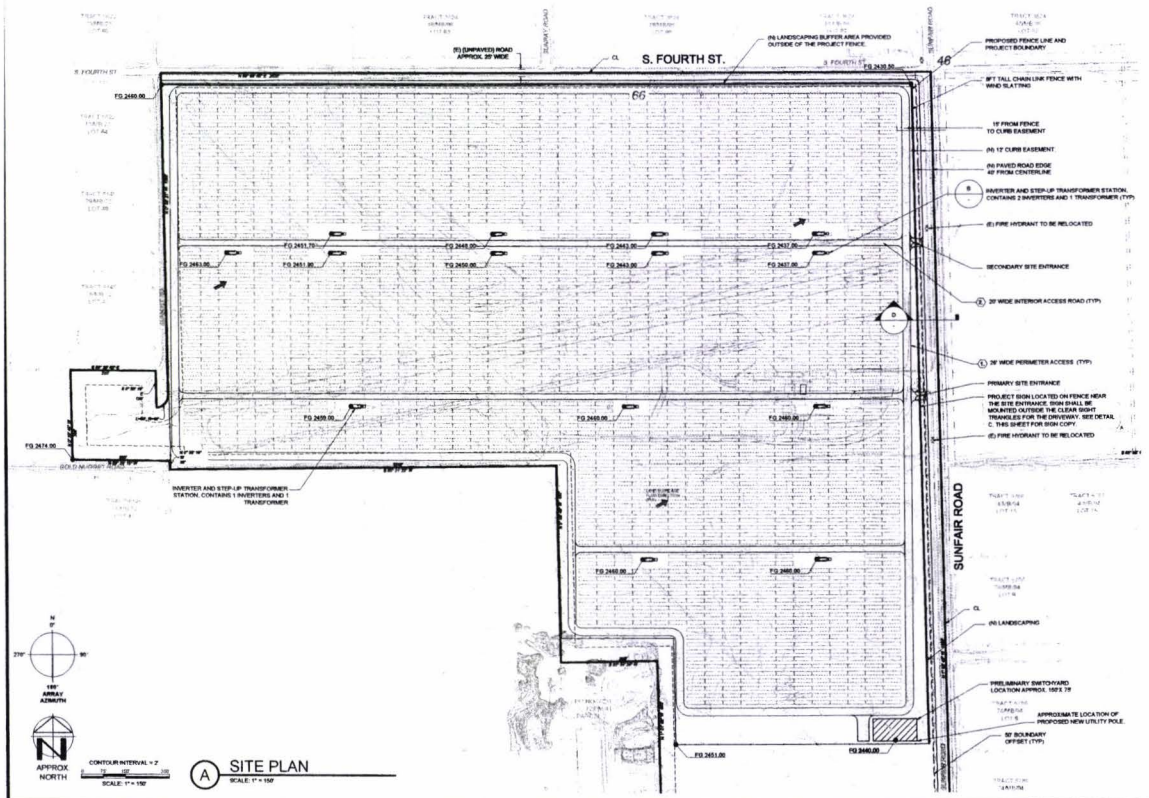
EASEMENTS ITEMS PER P.T.R. 997-23052913-ML3

1. WATER RIGHTS, CLAIMS OR TITLE TO WATER, WHETHER OR NOT DISCLOSED BY THE PUBLIC RECORDS - AFFECTS ALL PROPERTIES
2. RIGHTS OF PUBLIC IN ANY PORTION LYING WITHIN ROAD STREET, OR HIGHWAY
3. RESERVATIONS IN PATENT H/PATENTS/336
4. OPERATION & MAINTENANCE OF RR, RIGHT OF WAY FOR COUNTY ROADS, RIGHT TO USE WATER RISING UPON LAND, PER 4960/0295 (RESERVED ON PAGE 357 THEREOF)
5. 17' INGRESS/EGRESS & ROAD EASEMENT PER 6455/OR/32
6. 25' GENERAL TELEPHONE EASEMENT PER 7663/OR/411
7. 40' PUBLIC ROAD EASEMENT PER 93-251080 O.R. (OFFERED PER 93-029782 O.R.)
8. PUBLIC ROAD EASEMENT PER 93-113781 O.R (OFFERED PER 73PM49-41)
9. AIRPORT RUNWAY EXPANSION EASEMENT PER 93-094839 O.R.
10. RIGHTS OF THE PUBLIC OVER ANY PORTION LYING WITHIN A ROAD/HIGHWAY
11. CENTERLINE CALIFORNIA ELECTRIC POWER EASEMENT PER 2385/OR/268 (NO WIDTH GIVEN)
12. APPROX. CENTERLINE 8' WIDE SO. CA. EDISON EASEMENT PER 8035/OR/962 (DOC. HAS HAND WRITTEN NOTES)
13. 50' PUBLIC ROAD EASEMENT PER 806 \OR\521
14. 40' PUBLIC ROAD EASEMENT PER 2003-0555326
15. PUE PER 78/MB/71-72
16. CC&R's PER 5236/OR/435 BUILDING RESTRICTIONS (DOCUMENT STATES THAT THE PLANNING COMMISSION CAN RE-ZONE)
17. ELECTRIC POWER EASEMENT PER 5271/OR/15
18. PUBLIC ROAD EASEMENT PER 1998-0283415

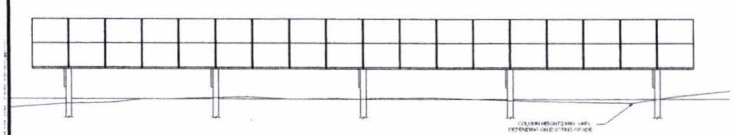
OTHER ITEMS LISTED WHICH AFFECT ALL PARCELS. ANY EASEMENTS NOT DISCLOSED BY PUBLIC RECORDS, MATTERS WHICH MAY BE DISCLOSED BY AN ALTA/ACSM SURVEY. RIGHTS OF PARTIES IN POSSESSION... REFER TO P.T.R.

THE DESIGN ASSUMES THAT ANY EASEMENTS EFFECTING THE SOLAR FIELD WILL BE VACATED PRIOR TO THE START OF CONSTRUCTION.



KEYED NOTES:

1. PERIMETER ACCESS: 26' WIDE CLEAR ACCESS WAY TO BE CONSTRUCTED USING APPROVED NATIVE MATERIAL OR GRAVEL, COMPACTED TO 85% COMPACTION.
2. INTERIOR ACCESS: 20' WIDE CLEAR ACCESS WAY TO BE CONSTRUCTED USING APPROVED NATIVE MATERIAL OR GRAVEL, COMPACTED TO 85% COMPACTION.



NOTES:

1. SAFETY LIGHTING WILL BE INSTALLED AT THE ENTRY GATES AND THE SWITCHGEAR LOCATION. A LIMITED AMOUNT OF LIGHTING WILL BE INSTALLED AND WILL BE DESIGNED TO PREVENT SPILLOVER INTO NEIGHBORING PROPERTIES. THERE WILL BE OPERABLE LIGHTING AT EACH CONVERSION STATION, BUT THESE UNITS WILL BE USED AS NEEDED AND WILL NOT TYPICALLY OPERATE AT NIGHT. THE ENTRY WILL HAVE FIXTURES TO PROVIDE MINIMAL LIGHTING AND WILL HAVE ADDITIONAL ON-DEMAND (E.G. TIMER) LIGHTING AS NEEDED OR REQUIRED.
2. GRUBBING AND GRADING ACTIVITIES WILL BE LIMITED DUE TO THE PREVIOUS DEVELOPMENT ACTIVITIES AND INHERENTLY SPARSE VEGETATION. SITE GRADING WILL BE SOLELY FOR STORM WATER CONTROL. THE PREVIOUS DEVELOPMENT SIGNIFICANTLY REDUCES THE NEED FOR SITE LEVELING, CUT AND FILL, AND OTHER INVASIVE SITE MODIFICATIONS. FOR THE VAST MAJORITY OF THE ARRAY AREA, NO SITE GRADING WILL BE EMPLOYED.
3. PLANT AND TREE PROTECTION: SPECIES IN THE JOSHUA TREE SOLAR PROJECT VICINITY THAT ARE SUBJECT TO PERMITTING INCLUDE JOSHUA TREE (YUCCA BREVIFOLIA) AND SEVERAL SPECIES OF CACTI (SILVER CHOLLA, BUCKHORN CHOLLA [CYLINDROPUNTIA ACANTHOCARPA], PENCIL CHOLLA [C. RAMOSISSIMA], AND BEAVERTAIL CACTUS [OPUNTIA BASILARIS]). PLEASE SEE *DESERT TORTOISE SURVEY AND GENERAL BIOLOGICAL RESOURCES ASSESSMENT FOR THE JOSHUA TREE SOLAR FARM (AIRPORT SITE) SAN BERNARDINO COUNTY, CA, 2012, TETRA TECH* FOR THE LOCATIONS OF THESE PLANTS. WHERE FEASIBLE AND PRACTICABLE, INDIVIDUAL PLANTS WILL BE SALVAGED AND USED FOR THE PROJECT'S REVEGETATION PROGRAM OR SALVAGED BY AN APPROVED NURSERY, LANDSCAPER, OR OTHER GROUP.
4. ALL EXISTING BUILDINGS TO BE REMOVED.

PRELIMINARY
NOT FOR CONSTRUCTION

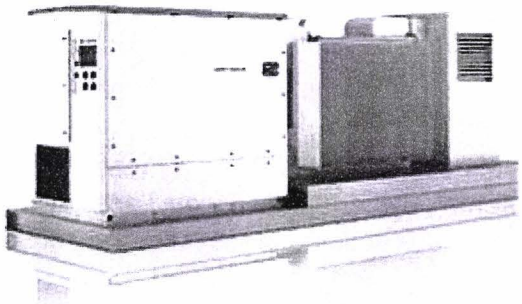

FIGURE 4: EXAMPLE MEDIUM-VOLTAGE INVERTER STATION

2.7 AC COLLECTION SYSTEM

The AC collection system is 33 kV, and all related equipment will be 35 kV class. The collection system is a network of either buried or aboveground cables appropriately sized to minimize energy loss. The system will effectively collect energy from the solar panels and transfer energy to the main collection switchgear, which will allow the energy to be transmitted to the electric grid. The project's current design is an underground collection system which will terminate at the switchgear, which will be separately enclosed with a security fence and lockable access gates.

2.8 DISTRIBUTION LINE IMPROVEMENTS

The distribution line improvements will be constructed, owned, and operated by SCE. The existing power poles on the west side of Sunfair Road will be reconductored to accommodate the new project. The utility line will be retrofitted by augmenting existing poles or by replacing poles. It may be necessary to replace the existing poles and that decision will be made by the SCE team.

The system will be designed and built by SCE, so all final design and engineering decisions will be made by SCE and fully supported by the project. A photograph of a typical upgraded pole structure is shown in Figure 5.

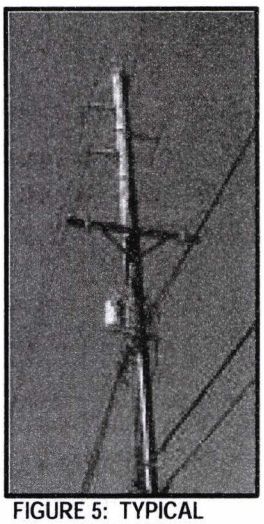

FIGURE 5: TYPICAL POLE STRUCTURE

2.9 ACCESS PATHS AND FENCING

Fencing will be installed around the perimeter of the site. The fencing is currently planned to be 8 feet tall and will be built in accordance with the County standards. Access roads will be constructed along the interior perimeter of the site and between the MW block solar arrays. Primary access to the project will be via a gate on Sunfair Road.

2.10 SAFETY LIGHTING

Safety lighting will be installed at the entry gates and the switchgear location. A limited amount of lighting will be installed and will be designed to prevent spillover into neighboring properties. There will be operable lighting at each conversion station, but these units will be used as

AR063251

needed and will not typically operate at night. The entry will have fixtures to provide minimal lighting and will have additional on-demand (e.g. timer) lighting as needed or required.

3.0 PROJECT CONSTRUCTION

Project construction work is expected to last for approximately six months and will consist of site preparation, site improvements, system installation, and system acceptance. The various phases of the construction cycle are outlined in the following sections.

3.1 SITE PREPARATION

Site preparation will involve the erection of a perimeter security fence, deconstruction or demolition of existing buildings, remediation of a few specific site conditions if applicable, and establishment of temporary utilities. The utility connections are already established to the site, making power and water connections readily available. Demolition of existing buildings will be the majority of site preparation. Where possible and feasible, materials from existing structures will be reused or recycled. All concrete structures (hangar aprons, foundations, and slabs) are expected to be demolished and removed. All other paved areas, including the existing runways, are expected to be left in place.

Grubbing and grading activities will be limited due to the previous development activities and inherently sparse vegetation. Prior to or concurrently with installing the security fencing, the site may include a desert tortoise exclusionary fence, or similar measures that may be recommended by the U.S. Fish and Wildlife Service or California Department of Fish and Wildlife.

3.2 CONSTRUCTION ACCESS

Construction vehicles will access the site via Sunfair Road on the eastern boundary of the site. The staging area and the laydown area will most likely be located just inside of the gate on the previously paved airport parking and taxi area. The main temporary logistics area of the site includes construction trailers, a first aid station, worker parking, truck loading and unloading areas, and areas for site assembly tasks. Portable toilet facilities will be installed for use by construction workers during the construction phase and will be serviced by a private company on a regular basis.

3.3 STORM WATER AND EROSION CONTROL

If required, a Storm Water Pollution Prevention Plan incorporating best management practices for erosion control will be prepared prior to the start of construction. During site preparation the Storm Water Pollution Prevention Plan will be implemented and initial erosion and sedimentation controls will be installed. In addition, water truck reloading stations will be established for dust control. No retention basins or ponds are currently planned for the project. The project will also comply with applicable water quality requirements adopted by the Regional Water Quality Control Board and the State Water Resources Control Board.

AR063252

3.4 SITE GRADING

The previous airport development significantly reduces the need for site leveling, cut and fill, and other site modifications. No site grading is planned for the majority of the array area; however, limited grading may be required for erosion or stormwater control to comply with permit conditions.

3.5 FACILITY INSTALLATION

The bulk of the project activities involve installation of major equipment, including array foundations (driven piers when practical), power stations, cable installation, and switchgear placement. Rack piers are usually driven into the ground at depths of 6 to 12 feet as dictated by the soils and the array structural design. The module racking assembly is connected to the piers. The modules are fastened to the racking assembly and electrically connected together in series strings. The strings will be routed to DC combiners at the ends of each array row and subsequently routed to the power conversion stations where the electricity is converted from DC to AC.

The AC collection system will be a series of cables, sized to minimize energy losses and to effectively collect and transfer energy to the project switchgear. The switchgear will be separately enclosed with a security fence and lockable access gates.

3.6 DISTRIBUTION LINE IMPROVEMENT CONSTRUCTION

SCE will be responsible for any distribution line necessary to serve the project. The distribution line improvement construction may include enhancement or replacement of the utility poles along Sunfair Road along with stringing of new overhead electrical cable and a tap to the distribution line on the south side of Twentynine Palms Highway. It is anticipated that the work areas needed for replacement of this line and the stringing of the new overhead electrical cable will be entirely included within the existing SCE easement.

3.7 CONSTRUCTION WASTE

Most construction waste is expected to be non-hazardous and to consist primarily of cardboard, wood pallets, copper and aluminum wire cut-offs, scrap steel, common trash, and wooden wire spools. Construction waste will be recycled wherever possible. Non-recyclable construction waste will be disposed of by a licensed contractor at an approved facility.

3.8 POTENTIALLY HAZARDOUS MATERIALS USED DURING PROJECT CONSTRUCTION

Construction equipment will utilize various hazardous materials such as hydraulic oil, diesel fuel, grease, lubricants, solvents, adhesives, paints, and other petroleum-based products contained in construction vehicles. All potentially hazardous materials will be contained, stored, and used in accordance with the manufacturers' instructions and handled in compliance with the applicable standards and regulations, such as those administered by the San Bernardino County Fire Department, Occupational Safety and Health Administration, and the California Occupational Safety and Health Administration.

AR063253

3.9 FUGITIVE DUST CONTROL

Short-Term Dust Generation

Construction activities including clearing, grading, excavating, and moving of heavy equipment will create fugitive dust at the site at various rates throughout the construction cycle. Any substantial fugitive dust is expected to be short-term and limited to the time period of early construction during the limited clearing and grading activities. The contractors will be required to comply with applicable Mojave Desert Air Quality Management District rules and policies. Dust may be controlled by covering stockpiles with tarps and water application which consists of trucks canvassing the site to apply water for dust suppression and soil conditioning. Water truck reloading stations may be established. After construction and during the operations period there is expected to be a minimal amount of fugitive dust.

Long-Term Dust Generation. The long-term operations associated with the project are not anticipated to generate a significant amount of dust.

3.10 CONSTRUCTION WATER REQUIREMENTS

Potable water for drinking and domestic needs will be either brought to the project site or provided by existing facilities serving the airport. Construction water needs will be limited to soil conditioning and dust suppression. Approximately 30 acre-feet of water will be required during construction and is expected to be obtained from Joshua Basin Water District via a nearby existing waterline co-located within the western bounds of Sunfair Road. Water truck reloading stations will be established on site and will be fed by this existing waterline.

3.11 CONSTRUCTION WORKERS, HOURS, AND EQUIPMENT

The construction workers will consist of laborers, electricians, supervisory personnel, support personnel, and construction management personnel. It is expected that most workers will commute to the site from nearby communities including Joshua Tree, Yucca Valley, Twentynine Palms, and Palm Springs. It is anticipated that there will be an average of 125 workers on site during the construction period with approximately 150 workers during certain phases.

Construction work will generally be done during daylight hours. Non-daylight work hours may be necessary to make up schedule deficiencies, or to complete critical construction activities. Construction activities will be conducted consistent with San Bernardino County Ordinance Section 83.01.080 and 83.01.090 regarding acceptable decibel levels.

Construction activities, duration, equipment, and workers are estimated below in Table 3.

Table 3: Estimated Construction Duration, Equipment and Workers by Activity

Activity	Duration	Equipment	Pieces	Workers
Demolition – existing structures and related infrastructure	1 Month	Backhoe	2	
		Bulldozer	1	
		5 cubic yard dump truck	2	

AR063254

Table 3: Estimated Construction Duration, Equipment and Workers by Activity

Activity	Duration	Equipment	Pieces	Workers
Site Preparation and Clearing/Grading	1 Month	Water Truck – 3 axles	3	Maximum – 150 Average – 125
		Grader	2	
		Bulldozer	1	
		25-Cubic Yard Paddle Scraper	1 (optional)	
		10-Ton Roller	2	
Desert Tortoise Fencing	2 Months	Bobcat	1	
		Trencher	1	
		Pick Up Truck	1	
Utility Upgrades	Intermittent, up to 6 Months	Line truck (with spool trailer)	1	
		Boom truck (with bucket)	2	
Underground Work	2 Months	Small Backhoe	2	
		Small Sheepsfoot Roller	2	
		Trencher	2	
		5-Cubic Yard Dump Truck	2	
		5kW Generator	2	
System Installation	3 Months	4x4 Forklift	4	
		Small Crane	1	
		ATV Vehicle	4	
		Pick-Up Truck	5	
		Pile Driver	2	
		5-kW Generator	4	
Testing/Commissioning	1 Month	Pick-Up Truck	2	
Clean Up/Restoration	1 Months	Grader	2	

The construction activities shown above in Table 3 will be overlapping in certain phases with a total construction time of approximately six months.

Truck activity will be regularly required only during the project's construction. The types of truck, number of trucks estimated to be on site daily, and their approximate gross weight are presented below.

Truck Type	Average on Site	Gross Weight
8,000 Gallon Water Truck	3	25 tons empty/50 tons full
5 CY Dump Truck	3	15,000 lbs
Pick-up Trucks	5	5,000 lbs
Pile Driver	2	7,500 lbs
Grader	2	40,000 lbs
Boom truck with bucket	2	16,000 lbs
Utility line service truck	1	35,000 lbs

AR063255

Periodic truck activity will be needed for routine maintenance and panel washing activities once the project is in operation.

3.12 TESTING, COMMISSIONING, AND ACCEPTANCE

Testing will happen throughout the PV facility installation at all stages. As each MW block is completed, the electrical components of the system will be tested as a subsystem at the functional level. Once all blocks are completed, the system will be interconnected to the SCE distribution system and each block will be commissioned again to test performance. This commissioning and testing period is expected to last approximately one month after interconnection to the SCE system.

3.13 SITE CLEANUP

There will be ongoing cleanup and recycling of materials during the construction phase. Industrial trash receptacles will be established in the temporary laydown area and will be emptied or interchanged throughout the construction of the project. Once the project is completed the site will be cleared of any remaining debris or materials and each will be recycled or disposed of appropriately.

4.0 PROJECT OPERATIONS, MAINTENANCE, AND DECOMMISSIONING

Once placed into service, the project will be operated on an unstaffed basis and monitored remotely with scheduled personnel visitations for security, maintenance, services, and system monitoring.

Brief weekly inspections are planned. Ongoing maintenance is expected to occur on a monthly basis and will be scheduled to avoid peak power demand periods, and unplanned maintenance will typically be responded to as needed depending on the event. Preventative maintenance kits and certain critical spares will be stored on-site, while all other components will be readily available from a remote warehouse facility.

4.1 MODULE CLEANING

Periodic array module washings will be scheduled and completed depending on the soiling conditions that will exist at the site, which could be up to 4 times per year. It is expected that less than 1 acre foot of water will be used per washing; this water may be supplied by the Joshua Basin Water District. Due to evaporation and onsite ground percolation, it is expected that no water from the washings will run offsite. Module cleaning will use conditioned water obtained from the closest source of adequate quality water.

4.2 POTENTIALLY HAZARDOUS MATERIALS USED DURING PROJECT OPERATIONS

The only potentially hazardous material within the fully operation site would be the mineral insulating oil in the step-up transformers. The transformer oil has low toxicity and is a fully bio-neutral, biodegradable fluid. In the case of a major transformer breach, oil would be captured in a built-in oil containment system suitably sized to accommodate the maximum possible spillage. Upon leakage failure, the seeped fluid would be removed by a certified vehicle and recapture system and the entire transformer would be replaced.

AR063256

4.3 PROJECT DECOMMISSIONING

A PV solar plant has a typical life of about 30 years. Once the useful life of the plant is exhausted, the plant could be refurbished to continue operating as a power plant or decommissioned and removed. If the system is to be removed, most of the materials (steel, aluminum, copper, and glass) would be recycled at nearby facilities. The materials that cannot be recycled, and those materials which contain any oil or lubricants, would be disposed of according to San Bernardino County Development Code Section 84.29.060 or other applicable development standards at the time of decommissioning. The amount of water used during decommissioning will be similar to the amount used during construction, primarily for dust control. The site could then be converted to other uses in accordance with applicable land use regulations.

San Bernardino County, 2014b. Draft "Solar Ordinance" amending Chapter 84.29, Renewable Energy Generation Facilities.

AR063258

Attachment A

Compliance with SB County Draft Solar Ordinance

AR063259

Compliance with San Bernardino Solar Ordinance- Findings of Fact		
1	The proposed commercial solar energy generation facility is either: (A) sufficiently separated from existing communities and existing/developing rural residential areas so as to avoid adverse effects, or (B) of a sufficiently small size, provided with adequate setbacks designed to be lower profile than otherwise permitted, and sufficiently screened from public view so as to not adversely affect the desirability and future development of communities, neighborhoods, and rural residential use	The Project site is 3.5 miles east of the city of Joshua Tree and 1.3 miles north of Twentynine Palms Highway in unincorporated San Bernardino County. The facility will be located on 115 acres, and will be screened with an 8 foot fence with landscaping along Sunfair Road.
2	Proposed fencing, walls, landscaping, and other perimeter features of the proposed commercial solar energy generation facility will minimize the visual impact of the project so as to blend with and be subordinate to the environment and character of the area where the facility is to be located.	The facility will be located on 115 acres, and will be screened with an 8 foot fence with landscaping as required by the County along Sunfair Road.
3	The siting and design of the proposed commercial solar energy generation facility will be either: (A) unobtrusive and not detract from the natural features, open space and visual qualities of the area as viewed from communities, rural residential uses, and major roadways and highways, or (B) located in such proximity to already disturbed lands, such as electrical substations, surface mining operations, landfills, wastewater treatment facilities, etc., that it will not further detract from the natural features, open space and visual qualities of the area as viewed from communities, rural residential uses, and major roadways and highways.	The siting of the project has been deliberately located on a deactivated airport, an already disturbed location. The project will have limited disturbance to native biological resources, including wildlife, vegetation, and soils.
4	The siting and design of project site access and maintenance roads have been incorporated in the visual analysis for the project and shall minimize visibility from public view points while providing needed access to the development site	Access will be along the existing Sunfair Road; no new transportation routes will need to be included in visual assessments.
5	The proposed commercial solar energy generation facility will not adversely affect the feasibility of financing infrastructure development in areas planned for infrastructure development or will be located within an area not planned for future infrastructure development (e.g., areas outside of water agency jurisdiction).	The project is not expected to adversely affect the feasibility of financing infrastructure development. The project is within the Joshua Basin Water District.
6	The proposed commercial solar energy generation facility will not adversely affect to a significant degree the availability of groundwater supplies for existing communities and existing and developing rural residential areas	Very little water will be used for the construction or operation of the project. Water for panel washing will occur up to 4 times per year and the water will be most likely be provided by the Joshua Basin Water District.

AR063260

Compliance with San Bernardino Solar Ordinance- Findings of Fact		
7	The proposed commercial solar energy generation facility will minimize site grading, excavating, and filling activities by being located on land where the existing grade does not exceed an average of five (5) percent across the developed portion of the project site, and by utilizing construction methods that minimize ground disturbance.	The topography of the project site is relatively flat, with slopes less than 1 %. Grading will be minimized because the site is a deactivated airport. Where possible, existing pavement and asphalt will be retained.
8	The proposed commercial solar energy generation facility will be located in proximity to existing electrical infrastructure, such as transmission lines, utility corridors, and roads, so that: (A) minimal ground disturbance and above ground infrastructure will be required to connect to the existing transmission grid, considering the location of the project site and the location and capacity of the transmission grid, (B) new electrical generation tie lines will be co-located on existing power poles whenever possible, and (C) existing rights-of-way and designated utility corridors will be utilized to the extent practicable.	The project will interconnect at the project boundary into the existing transmission system along Sunfair Road. No new ROW is needed for transmission.
9	The proposed commercial solar energy generation facility will be sited so as to avoid or minimize impacts to the habitat of special status species, including threatened, endangered, or rare species, Critical Habitat Areas as designated by the U.S. Fish and Wildlife Service, important habitat/wildlife linkages or areas of connectivity designated by County, state or federal agencies, and areas of Habitat Conservation Plans or Natural Community Conservation Plans that discourage or preclude development.	The siting of the project has been deliberately located on a deactivated airport, an already disturbed location. Very little vegetation or wildlife habitat exists at the project location.
10	Adequate provision has been made to maintain and promote native vegetation and avoid the proliferation of invasive weeds during and following construction.	Weeds will be managed during construction and operations.
11	The proposed commercial solar energy generation facility will be located so as to avoid or mitigate impacts to significant cultural and historic resources, as well as sacred landscapes.	A cultural resources survey has been conducted and there are no resources of significance.
12	The proposed commercial solar energy generation facility will be designed in a manner that does not impede flood flows, avoids substantial modification of natural water courses, and will not result in erosion or substantially affect area water quality.	The project is not sited in a floodplain; nor will it modify natural water course. The project site does not contain any washes or waters of the State.
13	The proposed commercial solar energy generation facility will not be located within a floodway designated by the Federal Emergency Management Agency (FEMA), has been evaluated for flood hazard impacts pursuant to Chapter 82.14 of the Development Code, and will not result in increased flood hazards to upstream or downstream properties	The project is not sited in a FEMA designated floodplain.

AR063261

Compliance with San Bernardino Solar Ordinance- Findings of Fact		
14	All on-site solar panels, switches, inverters, transformers, and substations shall be located at least one foot above the base flood elevation as shown on the Flood Insurance Rate Maps	Project features will be designed to be at least one foot above base flood elevation.
15	For development sites proposed on or adjacent to undeveloped alluvial fans, the commercial solar energy generation facility has been designed to avoid potential channel migration zones as demonstrated by a geomorphic assessment of the risk of existing channels migrating into the proposed development footprint, resulting in erosion impacts.	The project site does not contain any washes or waters of the State, and is not located on an alluvial fan.
16	For proposed facilities located on prime agricultural soils or land designated by the California Farmland Mapping and Monitoring Program as Prime Farmland, Unique Farmland, or Farmland of Statewide Importance, where use of the land for agricultural purposes is feasible, the proposed commercial solar energy generation facility will not substantially affect the agricultural viability of surrounding lands.	The project is not located on prime agricultural farmland. The project was deliberately sited on a deactivated airport to reduce environmental impacts.
17	If the proposed site is subject to a Williamson Act contract, the proposed commercial solar energy generation facility is consistent with the principals of compatibility set forth in California Government Code Section 51238.1.	The project is not subject to a Williamson Act contract.
18	The proposed commercial solar energy generation facility will not preclude access to significant mineral resources.	There are no known mineral resource conflicts with the project site.
19	The proposed commercial solar energy generation facility will avoid modification of scenic natural formations.	No scenic natural formations exist on the project site.
20	The proposed commercial solar energy generation facility will be designed, constructed, and operated so as to minimize dust generation, including provision of sufficient watering of excavated or graded soil during construction to prevent excessive dust. Watering will occur at a minimum of three (3) times daily on disturbed soil areas with active operations, unless dust is otherwise controlled by rainfall or use of a dust palliative, or other approved dust control measure.	Best management practices will ensure that dust is minimized during construction.
21	All clearing, grading, earth moving, and excavation activities will cease during period of winds greater than 20 miles per hour (averaged over one hour), or when dust plumes of 20 percent or greater opacity impact public roads, occupied structures, or neighboring property, and in conformance with Air Quality Management District (AQMD) regulations.	Construction activities and dust control will be performed in accordance with County and AQMD regulations.
22	For sites where the boundary of a new commercial solar energy generation facility will be located within one-quarter mile of a primary residential structure, an adequate wind barrier will be provided to reduce potentially blowing dust in the direction of the residence during construction and ongoing operation of the commercial solar energy generation facility	There are residences within ¼ mile to the north boundary of the project. An appropriate wind barrier will be included in the project design.

AR063262

Compliance with San Bernardino Solar Ordinance- Findings of Fact		
23	Any unpaved roads and access ways will be treated and maintained with a dust palliative or graveled or treated by another approved dust control method to prevent excessive dust, and paving requirements will be applied pursuant to Chapter 83.09 of the Development Code	Best management practices will be used on unpaved roads to control dust.
24	On-site vehicle speed will be limited to 15 miles per hour	Vehicle speeds will be limited to 15 miles per hour for unimproved roads on the project site.
25	For proposed commercial solar energy generation facilities within two (2) miles of the Joshua Tree National Park boundaries, the location, design, and operation of the proposed commercial solar energy generation facility will not be a predominant visual feature along the main access roads to the park (Park Boulevard and Utah Trail), nor will it substantially impair views from hiking/nature trails, campgrounds, and backcountry camping areas within the National Park	The project will not be seen from main roads within Joshua Tree National Park. There are no known designated hiking trails or camping areas within the Park where the project could be seen.
26	For proposed facilities within two (2) miles of the Mojave National Preserve boundaries, the location, design, and operation of the proposed commercial solar energy facility will not be a predominant visual feature of, nor substantially impair views from, hiking and backcountry camping areas within the National Preserve	The project is not within 2 miles of the Mojave National Preserve boundaries.
27	For proposed facilities within two (2) miles of Death Valley National Park boundaries, the location, design, and operation of the proposed commercial solar energy facility will not be a predominant visual feature of, nor substantially impair views from, hiking and backcountry camping areas within the National Park	The project is not within 2 miles of the Death Valley National Park.
28	For proposed facilities within two (2) miles of the boundaries of a County, state or federal agency designated wilderness area, the location, design, and operation of the proposed commercial solar energy facility will not be a predominant visual feature of, nor substantially impair views from, the designated wilderness area	The project is not within 2 miles of any known wilderness area.
29	For proposed facilities within two (2) miles of the boundaries of any active military base, the location, design, and operation of the proposed commercial solar energy facility will not substantially impair the mission of the facility	The project is not within 2 miles of a military base.
30	When located within a city's sphere of influence, in addition to other County requirements, the proposed commercial solar energy facility will also be consistent with relevant city zoning requirements that would be applied to similar facilities within the city.	The project is not known to be within Joshua Tree's sphere of influence.

Compliance with San Bernardino Solar Ordinance- Findings of Fact		
31	On terms and in an amount acceptable to the Director, adequate surety is provided for reclamation of commercial solar energy generation facility sites should energy production cease for a continuous period of 180 days and/or if the site is abandoned.	Adequate reclamation surety's will be discussed with the County and provided.

Introduction

The Yuma clapper rail (*Rallus longirostris yumanensis*) is federally endangered (U.S. Fish and Wildlife Service 1989), and the California black rail (*Laterallus jamaicensis coturniculus*) is listed as state endangered or state threatened throughout its range (Arizona Game and Fish Department 1988, California Department of Fish and Game 1994). The burrowing owl (*Athene cunicularia*) is listed as a Bird of National Conservation Concern by the U.S. Fish and Wildlife Service (2002) and is a species of special concern in California (California Department of Fish and Game 1994). Burrowing owls are declining in large portions of their North American breeding range, but populations have increased in the Imperial Valley of California between 1966-1996 (Sauer et al. 2002). Habitat loss and degradation have been identified as a primary threat to all three species (Evens et al. 1991, Eddleman and Conway 1998, Klute et al. 2003).

The California brown pelican (*Pelecanus occidentalis californicus*) is federally endangered (U.S. Fish and Wildlife Service 1983), but records of brown pelican have increased in California since the ban on DDT in 1972. Brown pelicans were first observed breeding in Salton Sea in June of 1996, but numbers at Salton Sea were set back by the botulism outbreak in the fall of 1996. Since then, nesting activity has been observed on a small rocky islet offshore of Obsidian Butte.

Mountain plovers (*Charadrius motanus*) are a species of special concern in California (California Department of Fish and Game 1994) and have been proposed for listing as federally threatened by the U.S. Fish and Wildlife Service. The Imperial Valley has one of the largest wintering populations of mountain plovers, but they do not breed in the Salton Sea area.

The following report summarizes the results of surveys conducted by the Arizona Cooperative Fish and Wildlife Research Unit in 2004, 2005, and 2006. Surveys were conducted to quantify relative abundance of Yuma clapper rails, California black rails, and burrowing owls in the project area for a proposed geothermal plant by CE Obsidian Energy LLC. We also looked for mountain plovers and brown pelicans during all surveys.

Study Area

The study area was located southeast of the Salton Sea in California's Imperial Valley and included a 305 meter (1000 foot) radius surrounding each of the 8 proposed well sites (OB1, OB2, OB3, OB4, OB5, OBI1, OBI2, OBI3; see Fig 1). With exception of the area surrounding OB3, the study area was dominated by irrigated agriculture. The area surrounding OB3, located on Obsidian Butte, consisted of sparse vegetation on an otherwise rocky landscape. The survey locations were identified in 2004 by examining the area within 305 meters of the 8 proposed well sites and the project site for potential rail or owl habitat. Areas were searched on foot or by vehicle. Areas were searched again in 2005 and 2006 so that any new habitat could be included in the 2005 and 2006 surveys. Burrowing owl habitat was located mainly adjacent to roadsides and irrigation canals. Four marshes were located and surveyed for both species of rails. All four

marshes were surveyed in 2004. The irrigation ditch was excluded from surveys in 2005 and 2006 because it does not contain suitable rail habitat. Descriptions of each marsh are provided below.

Union Pond

Union Pond is located on the southern end of the Salton Sea (Fig. 1). It was created by the Sonny Bono Salton Sea National Wildlife Refuge (SSNWR) and is managed for Yuma clapper rails. The pond is dominated by southern cattail (*Typha domingensis*). The only other vegetation present is sparse salt cedar (*Tamarix ramosissima*) on the edges of the pond. This area provides excellent habitat for Yuma clapper rails which prefer areas dominated by emergent plants such as southern cattail (Todd 1986, Conway et al. 1993). Union Pond is not currently optimal habitat for California black rails, which prefer shallow marshes dominated by common threesquare (*Schoenoplectus pungens*) and other emergent plants (Repking and Ohmart 1977, Conway et al. 2002).

Rock Hill Marsh

Rock Hill Marsh is a triangular-shaped wetland located on the eastern shore of the Salton Sea, north of Union Pond (Fig. 1). The marsh is separated from the Salton Sea by a levee and is supplied with agricultural runoff by a culvert on the southeastern corner of the marsh. The marsh was dominated by open water in 2004 but filled in with southern cattail in 2005 and 2006. The marsh was not optimal habitat for Yuma clapper rails and California black rails in 2004, but became much better habitat in 2005 and 2006 due to the growth of southern cattail.

McKendry Marsh

McKendry Marsh is located on the eastern shore of the Salton Sea, east of Obsidian Butte, and is separated from the Salton Sea by a levee (Fig. 1). The marsh is dominated by open water but contains small patches of southern cattail. The marsh is currently not optimal habitat for Yuma clapper rails or California black rails due to the amount and depth of the open water.

Irrigation Drainage Ditch

The irrigation ditch is located south of McKendry Marsh (Fig. 1) and is used to drain irrigation water from the surrounding agricultural fields. The ditch is approximately 5 meters wide and has steep sides vegetated by dense stands of common reed (*Phragmites occidentalis*). Cattail and bulrush are not present in the ditch. This ditch is not suitable habitat for Yuma clapper rails or California black rails due to the depth of the water, the steep sides, and the lack of suitable emergent vegetation.

Survey Methods

Yuma clapper rail surveys

We conducted at least 3 replicate call-broadcast surveys for Yuma clapper rails in McKendry Marsh, Union Pond, Rock Hill Marsh, and the irrigation drainage ditch in 2004 (Fig. 1). All replicate surveys were repeated in 2005 and 2006, except for the surveys along the irrigation drainage ditch (we concluded that the ditch lacked suitable habitat for rails in 2004). Survey points were distributed along the upland peripheries of the marshes at 150-m intervals. Surveyors got as close to the marsh vegetation as

possible at each survey point, and recorded the location of each survey point using a Global Positioning System (GPS) receiver. Each point was also marked with flagging tape and a wooden stake to assure replicate surveys were performed at exactly the same location. We used a portable CD player attached to a pair of amplified speakers. We taped the speakers together, placed them on the ground at the marsh edge, and faced them toward the marsh. We used standard USFWS survey protocols for Yuma clapper rails as per the January 2000 approved protocols. All surveys were replicated at least three times at each marsh from 13 April to 15 May in all three years. Each survey at each point included: an initial 1-min settling period, 2 min of call-broadcast, 2 min of passive listening, 2 min of call-broadcast, and 1 min of passive listening. The call-broadcast period consisted of pre-recorded calls of Yuma clapper rails being broadcast into the wetland at 80-90 decibels (measured 1m in front of the speaker) to elicit vocalizations. We used digital CD recordings of the 3 most-common breeding calls of Yuma clapper rails for the call-broadcast (*kek*, *clatter*, *kek-hurrah*). Surveyors recorded all rails heard and/or seen during the survey period at each point, and each rail was recorded on a separate line on the data sheet. We recorded whether each vocalization was part of a paired duet or was an isolated call, and whether each bird was detected at a previous survey point. We recorded the vegetative community where each bird was detected and drew the location of each bird on a map of the area. All replicate surveys were conducted in the morning (30 min before sunrise until 2 hours after sunrise) or evening (2 hours before sunset until 30 min after sunset). Surveys were conducted on days without rain and when wind speeds did not exceed 10 mph. We recorded percent cloud cover, wind speed, and ambient temperature at the beginning and end of each survey. We also recorded any events or disturbances that may have affected detection probability on each survey.

California black rail surveys

We conducted 5 replicate call-broadcast surveys for California black rails in McKendry Marsh, Union Pond, Rock Hill Marsh , and the irrigation drainage ditch in 2004 (Fig. 1). All replicate surveys were repeated in 2005 and 2006, except for surveys along the irrigation drainage ditch. Survey points were distributed along the upland peripheries of all emergent marshes at 50-m intervals. Surveyors got as close to the marsh vegetation as possible at each survey point, and recorded the location of each survey point using a GPS receiver. Each point was also marked with flagging tape and a wooden stake to assure replicate surveys were performed at exactly the same location on replicate surveys. We used a portable CD player attached to a pair of amplified speakers to broadcast black rail calls during each survey. We taped the speakers together, placed them on the ground at the marsh edge, and faced them toward the marsh. We used standard survey protocols for California black rails (Conway et al. 2002, Conway et al. 2004). All surveys were conducted between 10 April and 17 May in all three years. Each survey at each point included: an initial 3-min passive segment followed by a 3-min period of call-broadcast. The 3-min broadcast sequence consisted of three 1-min segments of 30 sec of black rail calls (15 sec of "*kic-kic-kerr*" calls and 15 sec of "*grr*" calls) followed by 30 sec of silence. The 30-sec call-broadcast period consisted of pre-recorded calls of California black rails being broadcast into the wetland at 80-90 decibels (measured 1m in front of the speaker) to elicit vocalizations. Surveyors recorded all rails heard and/or seen during the survey period at each point, and each rail was recorded on a separate line on the data sheet. We recorded whether each rail was detected at a previous survey point and the

vegetative community where each bird was detected. We marked the location of each bird on a map of the area. We also recorded whether each vocalization was part of a paired duet or was an isolated call. All replicate surveys were conducted in the morning (30 min before sunrise until 2 hours after sunrise) or evening (2 hours before sunset until 30 min after sunset). Surveys were conducted on days without rain and when wind speeds did not exceed 10 mph. We recorded percent cloud cover, wind speed, and ambient temperature at the beginning and end of each survey. We also recorded any events or disturbances that may have affected detection probability during each survey.

Burrowing owl surveys

We conducted standardized call-broadcast surveys for burrowing owls (Conway and Simon 2003, California Burrowing Owl Consortium 1997) along all passable roads within 1000 feet of the project site and well pads. Survey points were established along all roads and adjacent survey points were located 0.8 km apart unless local conditions warranted a closer distance (i.e., barriers or topography prevented observers from seeing all available habitat within 0.4 km). The permanent location of each survey point was recorded using a GPS receiver so that the exact survey location could be re-surveyed in future years. We conducted 4 replicate surveys in 2004 and 3 replicate surveys in both 2005 and 2006 at each survey point. Standardized burrowing owl surveys included an initial 3-min passive segment followed by a 3-min call-broadcast segment. The 3-min call-broadcast segment included a series of 30 sec call-broadcasts (*coo-coo* call and alarm call broadcast at 80-90 dB measured 1 m in front of the speaker) interspersed with 30 sec of silence. Surveys were restricted to the early morning (30 min before sunrise until 0800 hr) and evening hours (1800 until 30 min after sunset). Surveys were not conducted during rain or when wind speed was >20mph. At each point, observers recorded (1) the number of adult owls, (2) the number of juvenile owls, and (3) the number of presumed nest sites. We also conducted 4 replicate walking line-transect surveys in 2004 and 2 replicate walking line-transect surveys in both 2005 and 2006 in all areas that represented potential burrowing owl nesting habitat. Distance between adjacent transects was 30m unless local conditions warranted a closer distance. All burrows and burrowing owls located were marked onto maps of the area. The UTM coordinates of each burrow were recorded using a GPS receiver. In 2005 and 2006, we also placed a small identification tag at the entrance of the burrow, and revisited all previously detected burrows on each replicate survey. All surveys were conducted between 20 April and 17 May in all three years.

California Brown Pelicans

During all Yuma clapper rail and California black rail surveys, we also looked for California brown pelicans.

Mountain Plovers

During all burrowing owl surveys, we also looked for mountain plovers.

Survey Results

Yuma clapper rail surveys

In 2004, we conducted a total of 65 point-count surveys using the Yuma clapper rail protocol. Yuma clapper rails were detected in both Rock Hill Marsh and Union Pond with a mean number of 0.75 and 11.4 birds per survey, respectively (Table 1-3). Of the clapper rails detected, 67% were paired in Rock Hill Marsh and 46% were paired in Union Pond. We did not detect Yuma clapper rails in McKendry Marsh or the irrigation drainage ditch in 2004. California black rails were not detected during any of the Yuma clapper rail surveys.

In 2005, we conducted 47 point-count surveys using the Yuma clapper rail protocol. Yuma clapper rails were detected in Rock Hill Marsh, Union Pond, and McKendry Marsh with a mean number of 0.75, 10.2, and 0.33 birds per survey, respectively (Table 1-3). Of the clapper rails detected in Union Pond, 23% were paired. Pairs were not detected in Rock Hill Marsh or McKendry Marsh. California black rails were not detected during any of the Yuma clapper rail surveys.

In 2006, we conducted 33 point-count surveys using the Yuma clapper rail protocol. Yuma clapper rails were detected in Rock Hill Marsh, Union Pond, and McKendry Marsh with a mean number of 2.6, 20.3, and 1.3 birds per survey, respectively (Table 1-3). Of the clapper rails detected, 14%, 30%, and 17% were paired in Union Pond, Rock Hill Marsh, and McKendry Marsh respectively. California black rails were not detected during any of the Yuma clapper rail surveys.

California black rail surveys

In 2004, we conducted 225 point-count surveys using the California black rail protocol. California black rails were not detected at any of the survey points. Yuma clapper rails were detected in both Rock Hill Marsh and Union Pond with a mean number of 0.8 and 12.6 birds per survey, respectively (Table 1-3). Of the clapper rails detected, 50% were paired in Rock Hill Marsh and 44% were paired in Union Pond.

In 2005, we conducted 140 point-count surveys using the California black rail protocol. A single California black rail was detected in McKendry Marsh during 1 of the replicate surveys. We did not detect black rails at Union Pond or Rock Hill Marsh. Yuma clapper rails were detected in Rock Hill Marsh, Union Pond, and McKendry Marsh during our black rail surveys with a mean number of 1.6, 13.6, and 1.4 birds per survey, respectively (Table 1-3). Of the clapper rails detected, 29% were paired in McKendry Marsh, and 25% were paired in both Rock Hill Marsh and Union Pond.

In 2006, we conducted the same 140 point-count surveys using the California black rail protocol. California black rails were not detected at any of the survey points. Yuma clapper rails were detected in Rock Hill Marsh, Union Pond, and McKendry Marsh during our black rail surveys with a mean number of 2.8, 19.6, and 1.0 birds per survey, respectively (Table 1-3). Of the clapper rails detected, 0 were paired in McKendry Marsh, 21% were paired in Rock Hill Marsh, and 15% were paired in Union Pond.

Burrowing owl surveys

In 2004, we detected a total of 27 active burrowing owl burrows (Fig. 2-3, Table 4-5). Four of these burrows were found outside the 305 meter radius surrounding the well sites. Of the 27 detected burrows 54% were occupied by pairs, 39% were occupied by one adult, and 7% had signs of occupancy (i.e., feces or lining at the burrow entrance) but we didn't detect owls. We believe 40% (4 of 10) of the burrows where we observed only 1 adult, were actually occupied by a pair of owls, due to the presence of lining at the entrance of the burrow. The female was likely incubating at these burrows and was therefore not detected outside the burrow.

In 2005, we detected a total of 29 active burrowing owl burrows (Fig. 4-5, Table 4-5). Eight of these burrows were found outside the 305 meter radius surrounding the well sites. Of the 29 active burrows detected 48% were occupied by pairs, 20% were occupied by one adult, 13% had signs of occupancy (i.e., feces or lining at the burrow entrance) but we didn't detect owls, and we were unable to locate a burrow for 17% of the owls we detected during surveys. We believe 83% (5 of 6) of the burrows where we observed only 1 adult were actually occupied by a pair of owls. Of the active burrows detected in 2004, 48% were occupied or showed signs of occupancy during 2005, 23% were not occupied by owls, and 29% could not be relocated and were assumed to be destroyed or collapsed.

In 2006, we detected a total of 29 active burrowing owl burrows (Fig. 6-7, Table 4-5). Six of these burrows were found outside the 305 meter radius surrounding the well sites. Of the 29 active burrows detected 45% were occupied by pairs, 38% were occupied by one adult, and 17% had signs of occupancy (i.e., feces or lining at the burrow entrance). We believe 64% (7 or 11) of the burrows where we observed only 1 adult were actually occupied by a pair of owls. Of the active burrows detected in 2005, 48% were occupied or showed signs of occupancy during 2006, 14% were not occupied by owls, and 38% could not be relocated and were assumed to be destroyed or collapsed.

California Brown Pelicans

We did not detect any brown pelicans, or any obvious pelican roost trees, during any of our rail surveys in 2004, 2005, or 2006.

Mountain Plovers

We did not detect any mountain plovers during any of our burrowing owl surveys in 2004, 2005, or 2006.

11 December 2006

Dear Cooperator,

The following report is being submitted to fulfill the requirements of Federal Fish and Wildlife Permit number TE039466-1. This permit was issued to the Arizona Cooperative Fish and Wildlife Research Unit to conduct call-broadcast surveys for Yuma clapper rail and California black rail along the Lower Colorado River and All American Canal in Arizona and California and on the Salton Sea NWR in California. In 2006 we conducted surveys at 800 points. Each point received 3-10 replicate point-count surveys between March 6 and July 13. Point count surveys ranged from 6-10 minutes in length and included both a 3-5 minute silent period and 3-5 minute call-broadcast period. All detections of primary marsh bird species were recorded, including detections of California black rail and Yuma clapper rail.

In total we recorded 788 detections of California black rails and 1802 detections of Yuma clapper rails. These numbers include multiple detections of the same individuals (because we surveyed each marsh multiple times). The results of our survey efforts are summarized in the enclosed Excel spread sheet. Also enclosed is a digital copy of the report produced for Cal Obsidian Energy LLC, evaluating the potential effects of development on California black rail and Yuma clapper rail habitat in the Imperial Valley of California.

Although it is suggested in the permit, copies of field datasheets were not included with this report due to the volume of data collected. Copies of the approximately 1500 datasheets may be obtained upon request.

Sincerely,

Christopher Nadeau

Subject USFWS Permit Report

History: This message has been replied to.

Stacey,

I summarized our data in a few different ways in hopes that it will give you what you need. Please let me know if you need further information. I also attached maps created from 1:24000 USGS Topos.

Chris

History: This message has been replied to.

Stacey,

This was a glaring error on my part. We have been going around on this for so long I got confused as to which report we were discussing. I forgot I had sent
you the most up to date report. The attached table should replace the one I sent yesterday. Hopefully this table makes more sense.

Again, I apologize for the confusion,
Chris

DOS PALMAS CORE MARSH SURVEYS FOR YUMA CLAPPER RAIL AND CALIFORNIA BLACK RAIL

1.0 INTRODUCTION

AMEC Earth and Environmental, Inc. (AMEC) ornithologists conducted surveys for Yuma Clapper Rail (*Rallus longirostris yumanensis*) and California Black Rail (*Laterallus jamaicensis coturniculus*) in the 105 acre Dos Palmas Core Marsh in the spring of 2007. These 2007 surveys comprise the second year of on-going rail monitoring. Survey stations were established prior to the 2006 surveys. Photographs of these survey stations are in included in Appendix VI of this report.

The Core Marsh is part of the Bureau of Land Management's (BLM's) Dos Palmas Area of Critical Environmental Concern (ACEC), and is managed by the Center for Natural Lands Management (CNLM) (see Appendix I, Map 1).

The purpose of these surveys is the collection of baseline data regarding the current status and annual variations in the numbers of each species in the Dos Palmas Core Marsh, and, if practical, to provide information regarding habitat quantity, suitability, and use by the two rail species. The results of these surveys will be used as the baseline for monitoring change over time and will provide information for adaptive management strategies for the aquatic habitats in the Core Marsh. Marsh birds may be "indicator" species for assessing wetland ecosystem quality and restoration efforts.

1.1 Background

1.1.1 Yuma Clapper Rail

The Yuma Clapper Rail (*Rallus longirostris yumanensis*) is one of up to 21 subspecies of the widespread Clapper Rail (*Rallus longirostris*). The Yuma Clapper Rail is found in a "variety of marshy situations, from pure cattails and rushes to (marginally) stands of cane and flooded salt cedar" (Garrett and Dunn 1981). In the Imperial Valley and Salton Sea area the Yuma Clapper Rail is most common in freshwater marshes near the sea, but occurs locally "some distance from the sea at Dos Palmas Spring" (Garrett and Dunn 1981; see also AMEC 2006).

The Yuma Clapper Rail is a federally-listed Endangered species, and a California-listed Threatened species. Populations of Yuma Clapper Rails have undergone decline in the United States due to the destruction and degradation of freshwater marsh habitat.

The Yuma Clapper Rail is a slender, tawny-breasted bird with grayish edges on brown centered back feathers, olive wing coverts, vertical white bars on the flanks, a white stripe over the eye, and a long, partially orange bill.

1.1.2 California Black Rail

The Black Rail (*Laterallus jamaicensis*) is the smallest rail in North America. The California Black Rail (subspecies *coturniculus*) is a California-listed Threatened species, and, like the Yuma Clapper Rail, is found in marsh habitats and has been impacted by the loss and degradation of these habitats. Bulrush (*Scirpus* spp.) marshes seem to be favored in the Imperial Dam area (Garrett and Dunn 1981). The population of Black Rails in the Colorado River Valley between Needles, California and Yuma, Arizona was estimated to be 75-100 individuals in 1991 (Evens *et al.* 1991).

The California Black Rail is a rare to uncommon bird in the Salton Sea area, with most detections occurring in spring and summer, and its status considered "irregular and unpredictable" (Garrett and Dunn 1981). The uncertain status of the species makes it difficult to determine population dynamics, but there is evidence that canal lining projects have decreased habitat for the California Black Rail east of the Salton Sea (Evens et al. 1991).

The California Black Rail is blackish above with white speckling, has a chestnut nape, grayish-black underparts, narrow white barring on the flanks, and a short black bill.

2.0 SURVEY METHODOLOGY

AMEC ornithologists John F. Green, Chet McGaugh, and Stephen J. Myers made survey visits on six days in the spring of 2007 (see Table 1).

Table 1. Rail Surveys in the Dos Palmas Core Marsh in 2007.

Date	Route	Stations	Time	Surveyors
18 April	North	1-5	0556-0847	Green/McGaugh
27 April	West	16-21	0724-0908	Green/McGaugh
30 April	East	6-15	0557-0949	Green/McGaugh
18 May	North	1-5	0549-0707	McGaugh/Myers
25 May	West	16-21	0612-0750	Green/McGaugh
30 May	East	6-15	0548-0850	Green/McGaugh

McGaugh is permitted to take (harass by survey) Yuma Clapper Rails under Federal Fish and Wildlife Permit TE836517-5.

Yuma Clapper Rail and California Black Rail are included in the Memorandum of Understanding by and between AMEC Earth and Environmental, Inc. and the California Department of Fish and Game (expiration date: 31 October 2009).

Survey stations were established in 2006 based on accessibility, position relative to marsh habitat and position relative to other stations. Table 1 shows which stations were on each route (North, East, or West). The routes consisted of the stations surveyed on a particular day. Map 2 (Appendix I) shows the location of each of the stations. Each station was photographed (Appendix VI) and flagged, and a GPS waypoint was marked.

As Map 2 (Appendix I) indicates, the survey stations were almost completely on the perimeter of the marsh. It was decided that establishing points in the interior of the marsh would be very difficult, budget-consuming, hard to replicate, and potentially harmful to birds and their nests. In 2006, survey station 22, though clearly not deep into the Core Marsh, took 43 minutes to reach after completing the survey at station 21. Access required a level of "bushwhacking" not acceptable in habitat known to harbor sensitive species. This station was not surveyed in 2007. A route through the center of the Core Marsh may be desirable for future surveys, but considerable work, done prior to the survey/nesting season, would be necessary to establish interior marsh stations.

Two other survey stations, 6 and 7, were moved from their 2006 positions (Map 2) to minimize potential impacts to nesting birds. In 2006, station 7 provided the closest encounter with a clearly agitated Yuma Clapper Rail.

Yuma Clapper Rail

The "Yuma Clapper Rail Survey Protocol" (U.S. Fish and Wildlife Service 2000) establishes requirements for official surveys for the Yuma Clapper Rail. The protocol requires two surveys at each location to be conducted between 15 March and 31 May, with at least one week between surveys. Surveys are to be conducted between 30 minutes before sunrise until 3.5 hours after sunrise. Survey points should be 150-200 meters apart, depending on local conditions. Surveys should not be conducted if winds exceed 10 miles per hour.

The official Yuma Clapper Rail survey cassette tape was played at each station, with broadcast duration and sequence of listening periods as described in the protocol: two minutes broadcast, two minutes listen, two minutes broadcast, one minute listen, for a total survey time of seven minutes, not including a one minute period of listening prior to the first tape broadcast.

California Black Rail

Gibbs and Melvin (1993) posit that three surveys are necessary to confirm seasonal presence/absence for California Black Rails; Conway *et al.* (2002) recommend that the survey periods be 21-30 March, 21-30 April, and 21-30 May in the Lower Colorado River region. In 2007, AMEC conducted surveys in April and May; authorization for the surveys came too late for the March surveys.

Recorded California Black Rail vocalizations were played following each of the Yuma Clapper Rail survey periods. The standard California Black Rail protocol (Conway *et al.* 2002) provides a broadcast/listen regime of six minutes duration that begins with three minutes of silence, then alternates thirty second broadcast periods with thirty second periods of silence.

Equipment used included a cassette tape player, an iPod with external speaker, official Yuma Clapper Rail survey cassette tape, California Black Rail vocalization recordings, binoculars, two Global Positioning System (GPS) units, a digital SLR camera, and maps.

3.0 RESULTS

The results of the 2007 Dos Palmas Core Marsh surveys for Yuma Clapper Rail and California Black Rail are presented in Table 2. Table 3 presents the results from the 2006 surveys. Both data sets are presented here to allow for easy comparison between the two years of monitoring.

Yuma Clapper Rail

Yuma Clapper Rails were detected at 10 of 21 stations surveyed in 2007 (Table 2). In 2006 (Table 3) Yuma Clapper Rails were detected at 8 of 22 stations surveyed. Station 22 was not surveyed in 2007; access to the station is difficult and potentially harmful to marsh-nesting birds.

Each station was surveyed twice in 2007, in compliance with U.S. Fish and Wildlife Service protocol. Yuma Clapper Rail detections in the first round (April) were 8 at 21 stations, in May there were 9 detections at the 21 stations. These results compare very favorably to the 8 detections at 22 stations in 2006, when each station was surveyed only once.

No Yuma Clapper Rails were seen during the surveys. Both "clatter" calls and "kek" calls were heard. (See Appendix II, "Yuma Clapper Rail Survey Cover Sheets" and Appendix III, "Yuma Clapper Rail Survey Data Sheets").

Most of the Yuma Clapper Rails heard were 50m+ distance from the station, and the dense, tall vegetation made assessment of the vegetative and hydrological characteristics of the location the rail was calling from impossible.

California Black Rail

On 18 April, the first rail survey day of 2007, Green and McGaugh heard a California Black Rail call three times near survey station 5 (see survey data sheet, Appendix IV). The vocalizations were agitated "grrr" calls, and were initiated on the last silence segment of the broadcast regime. The bird was estimated to be approximately 35 meters from the survey station. After the survey period, a few extra vocalizations were broadcast for the purpose of 1) eliciting a response that might include the more familiar and frequently heard "kicky-doo" call, and 2) allow the observers to compare the bird's call with the recorded vocalizations. The California Black Rail did not respond.

The North route was repeated on 18 May, but no California Black Rails were detected.

As shown in Table 3, California Black Rails were not detected during the 2006 surveys.

We now know that California Black Rails use the Dos Palmas Core Marsh. Whether there is breeding or it is a migratory stopover has yet to be determined, and much of what is known about the status and distribution of this species in the region continues to be an "artifact of detectability" (Patten *et al.* 2003).

It is possible, and perhaps even likely, that the Dos Palmas Core Marsh has not yet been surveyed during the period when California Black Rails are most vocal. If three surveys provide 90% certainty of presence/absence, per Gibbs and Melvin (1993), missing the first survey period, possibly the "most vocal" period, could lower the accuracy of our results to an unacceptable level.

Other wetland bird species detected during the surveys include Virginia Rail, Sora, and Least Bittern. A complete list of bird species detected at Dos Palmas during the course of AMEC's rail surveys in 2007 is included as Appendix V.

Dos Palmas Core Marsh Rail Surveys: Bird Species List

amec

DOS PALMAS CORE MARSH RAIL SURVEYS: BIRD SPECIES LIST

This list reports only birds observed in the Dos Palmas area during the rail surveys conducted by AMEC in 2007, including travel (by foot) to rail survey stations, and related activities. Nomenclature and taxonomy generally follows the American Ornithologists' Union Checklist and its supplements.

SYMBOLS AND ABBREVIATIONS:

* Non-native species

** Sensitive species (State or Federally Listed as Threatened or Endangered, or a CDFG Species of Special Concern, or a USFWS Bird of Conservation Concern)

BIRDS	CLASS AVES
Ducks, Geese, and Swans	**Family Anatidae**
Mallard	*Anas platyrhynchos*
Cinnamon Teal	*Anas cyanoptera*
Ring-necked Duck	*Aythya collaris*
Ruddy Duck	*Oxyura jamaicensis*
Cormorants	**Family Phalacrocoracidae**
Double-crested Cormorant	*Phalacrocorax auritus*
New World Quail	**Family Odontophoridae**
Gambel's Quail	*Callipepla gambelii*
Grebes	**Family Podicipedidae**
Pied-billed Grebe	*Podilymbus podiceps*
Herons, Bitterns, and Allies	**Family Ardeidae**
**Least Bittern	*Ixobrychus exilis*
Great Blue Heron	*Ardea herodias*
Ibises and Spoonbills	**Family Threskiornithidae**
White-faced Ibis	*Plegadis chihi*
New World Vultures	**Family Cathartidae**
Turkey Vulture	*Cathartes aura*
Hawks, Kites, Eagles, and Allies	**Family Accipitridae**
**Sharp-shinned Hawk	*Accipiter striatus*
Rails, Gallinules, and Coots	**Family Rallidae**
**Yuma Clapper Rail	*Rallus longirostris yumanensis*
Virginia Rail	*Rallus limicola*
**California Black Rail	*Laterallus jamaicensis coturniculus*
Sora	*Porzana carolina*
Common Moorhen	*Gallinula chloropus*
American Coot	*Fulica americana*

Lapwings and Plovers	**Family Charadriidae**
Killdeer	*Charadrius vociferus*
Sandpipers, Phalaropes, and Allies	**Family Scolopacidae**
Greater Yellowlegs	*Tringa melanoleuca*
Pigeons and Doves	**Family Columbidae**
White-winged Dove	*Zenaida asiatica*
Mourning Dove	*Zenaida macroura*
Goatsuckers	**Family Caprimulgidae**
Lesser Nighthawk	*Chordeiles acutipennis*
Swifts	**Family Apodidae**
White-throated Swift	*Aeronautes saxatalis*
Rollers, Motmots, Kingfishers and Allies	**Family Coraciiformes**
Belted Kingfisher	*Ceryle halcyonl*
Woodpeckers and Allies	**Family Picidae**
Ladder-backed Woodpecker	*Picoides scalaris*
Tyrant Flycatchers	**Family Tyrannidae**
**Olive-sided Flycatcher	*Contopus cooperi*
Western Wood-Pewee	*Contopus sordidulus*
**Willow Flycatcher	*Empidonax traillii*
Hammond's Flycatcher	*Empidonax hammondii*
Gray Flycatcher	*Empidonax wrightii*
Dusky Flycatcher	*Empidonax olberholseri*
"Western" Flycatcher	*Empidonax* sp.
Black Phoebe	*Sayornis nigricans*
Ash-throated Flycatcher	*Myiarchus cinerascens*
Western Kingbird	*Tyrannus verticalis*
Shrikes	**Family Laniidae**
**Loggerhead Shrike	*Lanius ludovicianus*
Vireos	**Family Vireonidae**
Cassin's Vireo	*Vireo cassini*
Warbling Vireo	*Vireo gilvus*
Crows and Jays	**Family Corvidae**
Common Raven	*Corvus corax*
Swallows	**Family Hirundinidae**
Tree Swallow	*Tachycineta bicolor*
Northern Rough-winged Swallow	*Stelgidopteryx serripennis*
Cliff Swallow	*Petrochelidon pyrrhonota*
Barn Swallow	*Hirundo rustica*
Penduline Tits and Verdins	**Family Remizidae**
Verdin	*Auriparus flaviceps*

Wrens	**Family Troglodytidae**
Cactus Wren	*Campylorhynchus brunneicapillus*
Marsh Wren	*Cistothorus palustris*
Old World Warblers and Gnatcatchers	**Family Sylviidae**
Black-tailed Gnatcatcher	*Polioptila melanura*
Mockingbirds and Thashers	**Family Mimidae**
Crissal Thrasher	*Toxostoma crissale*
Starlings	**Family Sturnidae**
*European Starling	*Sturnus vulgaris*
Silky-flycatchers	**Family Ptilogonatidae**
Phainopepla	*Phainopepla nitens*
Wood-Warblers	**Family Parulidae**
Orange-crowned Warbler	*Vermivora celata*
Yellow Warbler	*Dendroica petechia*
Yellow-rumped Warbler	*Dendroica coronata*
Black-throated Gray Warbler	*Dendroica nigrescens*
Common Yellowthroat	*Geothlypis trichas*
Wilson's Warbler	*Wilsonia pusilla*
**Yellow-breasted Chat	*Icteria virens*
Tanagers	**Family Thraupidae**
Western Tanager	*Piranga ludoviciana*
Emberizids	**Family Emberizidae**
Abert's Towhee	*Pipilo aberti*
Brewer's Sparrow	*Spizella breweri*
Vesper Sparrow	*Pooecetes gramineus*
Song Sparrow	*Melospiza melodia*
Lincoln's Sparrow	*Melospiza lincolnii*
White-crowned Sparrow	*Zonotrichia leucophrys*
Cardinals, Saltators, and Allies	**Family Cardinalidae**
Black-headed Grosbeak	*Pheucticus melanocephalus*
Lazuli Bunting	*Passerina amoena*
Blackbirds	**Family Icteridae**
Red-winged Blackbird	*Agelaius phoeniceus*
Yellow-headed Blackbird	*Xanthocephalus xanthocephalus*
Great-tailed Grackle	*Quiscalus mexicanus*
Brown-headed Cowbird	*Molothrus ater*
Bullock's Oriole	*Icterus bullockii*
Fringilline & Cardueline Finches & Allies	**Family Fringillidae**
House Finch	*Carpodacus mexicanus*

Subject: ***Focused Least Bell's Vireo and Southwestern Willow Flycatcher Survey Report for the Salton Sea Species Conservation Habitat Project, Imperial County, California***

Dear Recovery Permit Coordinator:

This report documents the results of eight protocol-level presence/absence surveys for the state- and federally listed endangered least Bell's vireo (*Vireo bellii pusillus*), and the state- and federally listed endangered southwestern willow flycatcher (*Empidonax traillii extimus*). These focused surveys included approximately 248 acres of suitable habitat within the Salton Sea Species Conservation Habitat project site and adjacent upstream and downstream areas. The surveys were conducted in all areas of suitable least Bell's vireo and southwestern willow flycatcher habitat.

The southwestern willow flycatcher and least Bell's vireo are closely associated with riparian habitats, especially densely vegetated willow scrub and riparian forest vegetation. These species are threatened primarily by loss, degradation, and fragmentation of riparian habitats. They also are impacted by brown-headed cowbird (*Molothrus ater*) nest parasitism.

LOCATION AND EXISTING CONDITIONS

The approximately 248-acre survey area is situated within Imperial County, California (Figure 1) and lies within the U.S. Geological Survey (USGS) 7.5-minute map, Niland and Westmorland West Quadrangles: Section 5, Township 12 South, Range 13 East; Principal Meridian: San Bernardino; latitude 33°9'14.8" N; and longitude 115°38'24.0" W (Figure 2). The project site is slightly sloped with gradients from the southeast to the northwest. For the Alamo River portion of the survey, the elevation ranges from a high of -221 feet above mean sea level (AMSL) near the southeast portion to approximately -231 feet AMSL near the northwest portion. For the New River portion of the survey, the elevation ranges from a high of -216 feet AMSL near the southeast portion to approximately -228 feet AMSL near the northwest portion

VEGETATION COMMUNITIES

Tamarisk riparian habitat was the only vegetation community identified in the study area that was considered potentially suitable habitat for least Bell's vireo and southwestern willow flycatcher. This vegetation community is described below and shown as the survey area on Figure 3.

Tamarisk Riparian Habitat (248 acres)

According to Holland (1986), tamarisk habitat is a weedy, monoculture of any of several Tamarix species, usually supplanting native vegetation following a major disturbance. This habitat is usually found in sandy or gravelly braided washes or intermittent streams. Common species include narrowleaf willow (*Salix exigua*), big salt bush (*Atriplex lentiformis*), salt grass (*Distichilis spicata*), tamarisk (*Tamarix* sp.), and arrowweed (*Pluchea sericea*). Tamarisk often occupies jurisdictional wetlands.

Tamarisk habitat occurs throughout the survey area. Within the survey area, this community is characterized by monotypic stands of tamarisk interspersed with patches of fresh and brackish water marsh and stands of common reed (*Phragmites* sp.). The tamarisk habitat occurs in association with the two main rivers that empty into the Salton Sea: New River and Alamo River. The habitat occurs along the edges of the rivers often as a very narrow band of vegetation. In some areas the tamarisk scrub widens out and forms more of a patch of habitat versus a linear strip of vegetation. The narrow linear strips of tamarisk average 30 to 50 feet wide and patches of habitat range from 2 to 4 acres with an approximately 50-acre patch south of the New River.

METHODS

Focused surveys for the least Bell's vireo and southwestern willow flycatcher were conducted for the project on May 20, 21, 27, June 2, 3, 4, 10, 11, 18, 28, 29, and July 8, 9, 19, 20, 28, 29, and 30, 2010, by Paul M. Lemons, Brock A. Ortega, Jeffrey D. Priest, Stuart F. Fraser, Patricia Schuyler, Kamarul J. Muri, and Anita M. Hayworth, Ph.D (Table 1).

Dr. Hayworth, Mr. Ortega, Mr. Priest, and Mr. Lemons hold federal permits to conduct surveys for the southwestern willow flycatcher under TE-781084, TE-813545, TE-840619, and TE-051248, respectively. A federal recovery permit is not required to conduct surveys for the least Bell's vireo. All surveys conducted by Mr. Fraser, Mr. Muri, and Ms. Schuyler, as well as any surveys conducted after the survey period for southwestern willow flycatcher, were focused on the detection of least Bell's vireo; For the surveys when both species could be present, the

permitted biologist simultaneously focused survey efforts on the southwestern willow flycatcher and least Bell's vireo.

For the least Bell's vireo, eight site visits were conducted with at least 10-day intervals between visits except for two of the visits as described below, following the currently accepted U.S. Fish and Wildlife Service (USFWS) protocol (USFWS 2001). For the second and third visits, due to time delays with the authorization from California Department of Fish and Game to conduct the surveys, the interval was seven or eight days; the interval for the balance of the surveys was 10 days per the protocol. The site visits are generally conducted 10 days apart to maximize the detection of early and late arrivals, females, non-vocal birds, and nesting pairs. Surveys were conducted between dawn and approximately noon and were not conducted during periods of excessive or abnormal cold, heat, wind, rain, or other inclement weather. Typically, per the protocol, the survey should be ended at 11 a.m.; however, if birds continued to vocalize and winds remained mild, the survey was continued to its completion. Surveys were conducted between April 10 and July 31, as dictated in the protocol.

For the southwestern willow flycatcher, five surveys are required per *A Natural History Summary and survey protocol for the Southwestern Willow Flycatcher* issued by the USGS and U.S. Department of the Interior and approved by the USFWS (Sogge et al. 2010). For the 2010 protocol, five survey visits are required with one visit between May 15 and May 31, two visits between June 1 and June 24, and two visits between June 25 and July 17 (Sogge et al. 2010). Each survey visit was separated by at least five days. Because the habitat requirements for the two species overlap, surveys conducted between May 15 and July 17 include surveys for both species. A tape of recorded southwestern willow flycatcher vocalizations was used as described in the protocol. The biologist paused quietly for one to two minutes listening for flycatcher calls and songs. The tape of the vocalizations was then played for 10 to 15 seconds followed by a one to two minute listening period. This was repeated approximately every 50 to 100 feet within suitable habitat to induce southwestern willow flycatcher responses. When a southwestern willow flycatcher was detected, playing of the tape ceased to avoid harassment and the biologist did not start playing the tape again until approximately 120 feet away from the detected flycatcher. Various subspecies of this species are not easily differentiated visually or by call or song in the field, and any resident willow flycatchers observed in the final survey period would be assumed to be the "southwestern" subspecies. Non-resident willow flycatchers (those not observed during the third survey period) were assumed to be migrant willow flycatchers. Surveys for the southwestern flycatcher were conducted under Section 10(a), Permit Numbers TE-781084, TE-813545, TE-840619, and TE-051248.

The survey method consisted of slowly walking a systematic, meandering transect within and adjacent to all suitable habitat (i.e., tamarisk scrub) in the study area. This route was arranged to cover all suitable habitat on site. The vegetation along the New and Alamo rivers is composed of a combination of a narrow stringer of trees to larger patches or polygons of trees with a relatively dense understory. Where the vegetation was composed of the narrow open line of tamarisk, the observer moved through relatively quickly since the vegetation was generally composed of the open channel of the river with no overstory or shading, a strip of emergent vegetation, a narrow strip of medium height tamarisk and then the levee or berm. Hence the vegetation is less suitable for either of the riparian bird species. Where the habitat widened out or became dense, the observed spent time listening and searching for vocalizations or activity of least Bell's vireo or willow flycatcher. The survey area was split into three regions and eight full visits were made to each region. The three regions were determined based on the acreage covered with the survey and the access needed to cover the survey area in the time needed. Thus the acreage covered was approximately 77 acres for the Alamo River "A", 92 acres for the New River "A", and 79 acres for the New River "B"/Alamo River "B" survey areas. The total length cover for each area was as follows: 3.2 km for the Alamo River "A", 3.4 km for the New River "A" and 3.2 km for the New River "B"/Alamo River "B" with some areas of narrow or unsuitable habitat interspersed with areas of suitable habitat as described above. A vegetation map (scale 1 inch=200 feet) of the survey area was available to record any detected southwestern willow flycatcher or least Bell's vireo. Binoculars (10×40, 8×42) were used to aid in detecting and identifying wildlife species.

Weather conditions, time of day and season were appropriate for the detection of southwestern willow flycatcher and least Bell's vireo (Table 1).

Table 1
Schedule of Surveys

Date	Location*	Hours	Focus	Personnel	Conditions
5/20/10	Alamo River A	0530–1100	WIFL/LBVI	AMH	clear skies; 3–5 mph winds; 68°F–88°F

Survey Designations: LBVI: Least Bell's vireo; WIFL: willow flycatcher
Personnel Key: AMH: Anita Hayworth; BAO: Brock Ortega; JDP: Jeffrey Priest; KJM: Kamarul Muri; PCS: Patricia Schuyler; PML: Paul Lemons; SFF: Stuart Fraser
*In the field notes recorded by Dudek biologists, the New River B/Alamo River B survey area is listed as "New River B". The biologist covered the required survey area for New River B/Alamo River B during each survey regardless of how it was listed in the field notes.

RESULTS

The surveys for the state- and federally listed endangered least Bell's vireo were negative. Based on the migratory route of the species and the breeding locations, it is unlikely that the species occurs in this region; however there is some habitat that is suitable for them for both breeding and migratory stopover.

The state-listed endangered willow flycatcher was identified in riparian vegetation in the survey area during the 2010 focused surveys. A total of 27 observations were made of willow flycatcher within the survey areas adjacent to the Salton Sea (Figures 3–5; Table 2).

Table 2
Survey Results

Survey Pass	Date	Survey Area	Number of willow flycatcher individuals observed
1	5/20/2010	Alamo A	1
	5/21/2010	New River A	4

5	7/8/10	Alamo River A	0
	7/9/10	New River A	0
	7/9/10	New River B/Alamo River B	0
		Total	**27**

They were generally observed within patches of tamarisk where it was more than just a linear string of trees. They were observed along the New and Alamo rivers within the survey area of each river as well as in a patch of habitat located south of the New River. No southwestern willow flycatchers were observed during the third survey period. Thus it was concluded that southwestern willow flycatcher is not breeding within the study area. The willow flycatcher that was observed during this focused survey could be either one of the other subspecies of willow flycatcher that breed elsewhere or it could be a southwestern willow flycatcher that was migrating through the region and did not remain on site to breed. Based on the discussion of the occurrence of the various subspecies of willow flycatcher in *Birds of Salton Sea* and the dark plumage of the individuals that were detected, the subspecies occurring in this region is likely the little willow flycatcher (*E. t. brewsteri*) (Patten et al. 2002).

A total of 115 wildlife species were detected in the study area during general and focused surveys of the site (Appendix A). Common bird species observed include song sparrow (*Melospiza melodia*), Abert's towhee (*Melozone aberti*), verdin (*Auriparus flaviceps*), house finch

(*Carpodacus mexicanus*), seabirds/shorebirds including a variety of gulls and terns, aquatic birds including pelicans and cormorants, and wading birds including herons and egrets, the names of which are provided in a list in Appendix A.

The Willow Flycatcher Survey and Detection Form (Sogge et al. 2010) was filled out for each visit and is included in Appendix B. Site photographs are included in Appendix C.

Please feel free to contact me at 760.479.4239 with questions or if you require additional information.

I certify that the information in this survey report and attached exhibits fully and accurately represents my work.

APPENDIX A

Wildlife Species Observed on the Project Site

APPENDIX A
Wildlife Species Observed on the Project Site

WILDLIFE SPECIES – VERTEBRATES

BIRDS

ACCIPITRIDAE **– HAWKS, KITES, EAGLES, AND ALLIES**

Buteo jamaicensis – red-tailed hawk
Circus cyaneus – northern harrier
Haliaeetus leucocephalus – bald eagle
Parabuteo unicinctus – Harris's hawk

AEGITHALIDAE **– LONG-TAILED TITS AND BUSHTITS**

Psaltriparus minimus – bushtit

ANATIDAE **– DUCKS, GEESE, AND SWANS**

Anas acuta – northern pintail
Anas clypeata – northern shoveler
Anas cyanoptera – cinnamon teal
Anas platyrhynchos – mallard
Aythya affinis – lesser scaup
Aythya americana – redhead
Oxyura jamaicensis – ruddy duck

ARDEIDAE **– HERONS, BITTERNS, AND ALLIES**

Ardea alba – great egret
Ardea herodias – great blue heron
Botaurus lentiginosus – American bittern
Bubulcus ibis – cattle egret
Butorides virescens – green heron
Egretta thula – snowy egret
Ixobrychus exilis – least bittern
Nycticorax nycticorax – black-crowned night-heron

CAPRIMULGIDAE **– GOATSUCKERS**

Chordeiles acutipennis – lesser nighthawk

CARDINALIDAE **– CARDINALS AND ALLIES**

Passerina caerulea – blue grosbeak

CATHARTIDAE **– NEW WORLD VULTURES**

Cathartes aura – turkey vulture

APPENDIX A (Continued)

CHARADRIIDAE **– LAPWINGS AND PLOVERS**

Charadrius alexandrinus – snowy plover
Charadrius semipalmatus – semipalmated plover
Charadrius vociferus – killdeer

CICONIIDAE **– STORKS**

Mycteria Americana – wood stork

COLUMBIDAE **– PIGEONS AND DOVES**

Columba livia – rock pigeon
Columbina passerina – common ground-dove
Streptopelia risoria – ringed turtle dove
Zenaida asiatica – white-winged dove
Streptopelia decaocto – Eurasian collared-dove
Zenaida macroura – mourning dove

CORVIDAE **– CROWS AND JAYS**

Corvus brachyrhynchos – American crow
Corvus corax – common raven

CUCULIDAE **– CUCKOOS, ROADRUNNERS, AND ANIS**

Geococcyx californianus – greater roadrunner

EMBERIZIDAE **– EMBERIZIDS**

Passerculus sandwichensis – savannah sparrow
Melospiza lincolnii – Lincoln's sparrow
Melospiza melodia – song sparrow
Melozone aberti – Abert's towhee

FALCONIDAE **– CARACARAS AND FALCONS**

Falco peregrinus – peregrine falcon
Falco sparverius – American kestrel

FRINGILLIDAE **– FRINGILLINE AND CARDUELINE FINCHES AND ALLIES**

Carpodacus mexicanus – house finch
Spinus psaltria – lesser goldfinch

HIRUNDINIDAE **– SWALLOWS**

Petrochelidon pyrrhonota – cliff swallow
Stelgidopteryx serripennis – northern rough-winged swallow

APPENDIX A (Continued)

Tachycineta bicolor – tree swallow
Tachycineta thalassina – violet-green swallow

***ICTERIDAE* – BLACKBIRDS**

Agelaius phoeniceus – red-winged blackbird
Euphagus cyanocephalus – Brewer's blackbird
Icterus bullockii – Bullock's oriole
Molothrus ater – brown-headed cowbird
Quiscalus mexicanus – great-tailed grackle
Sturnella neglecta – western meadowlark
Xanthocephalus xanthocephalus – yellow-headed blackbird

***LANIIDAE* – SHRIKES**

Lanius ludovicianus – loggerhead shrike

***LARIDAE* – GULLS, TERNS, AND SKIMMERS**

Chlidonias niger – black tern
Chroicocephalus philadelphia – Bonaparte's gull
Gelochelidon nilotica – gull-billed tern
Hydroprogne caspia – Caspian tern
Larus californicus – California gull
Larus delawarensis – ring-billed gull
Larus livens – yellow-footed gull
Leucophaeus atricilla – Laughing Gull
Rynchops niger – black skimmer
Sterna forsteri – Forster's tern
Thalasseus elegans – elegant tern

***MIMIDAE* – MOCKINGBIRDS AND THRASHERS**

Mimus polyglottos – northern mockingbird

***ODONTOPHORIDAE* – NEW WORLD QUAIL**

Callipepla gambelii – Gambel's quail

***PARULIDAE* – WOOD-WARBLERS**

Dendroica petechia – yellow warbler
Geothlypis trichas – common yellowthroat
Icteria virens – yellow-breasted chat
Oreothlypis celata – orange-crowned warbler

APPENDIX A (Continued)

PELECANIDAE **– PELICANS**

Pelecanus erythrorhynchos – American white pelican
Pelecanus occidentalis – brown pelican

PHALACROCORACIDAE **– CORMORANTS**

Phalacrocorax auritus – double-crested cormorant

PHASIANIDAE **– PARTRIGES, GROUSE, TURKEYS, AND OLD WORLD QUAIL**

Phasianus colchicus – ring-necked pheasant

PICIDAE **– WOODPECKERS AND ALLIES**

Picoides scalaris – ladder-backed woodpecker

PODICIPEDIDAE **– GREBES**

Aechmophorus clarkii – Clark's grebe
Aechmophorus occidentalis – western grebe
Podilymbus podiceps – pied-billed grebe

POLIOPTILIDAE **– GNATCATCHERS AND GNATWRENS**

Polioptila melanura – black-tailed gnatcatcher

RALLIDAE **– RAILS, GALLINULES, AND COOTS**

Fulica americana – American coot
Gallinula chloropus – common moorhen
Porzana carolina – sora
Rallus longirostris yumanensis – Yuma clapper rail

RECURVIROSTRIDAE **– STILTS & AVOCETS**

Himantopus mexicanus – black-necked stilt
Recurvirostra americana – American avocet

REMIZIDAE **– PENDULINE TITS AND VERDINS**

Auriparus flaviceps – verdin

SCOLOPACIDAE **– SANDPIPERS, PHALAROPES, AND ALLIES**

Arenaria interpres – ruddy turnstone
Calidris mauri – western sandpiper
Limosa fedoa – marbled godwit
Limnodromus griseus – short-billed dowitcher
Limnodromus scolopaceus – long-billed dowitcher
Numenius americanus – long-billed curlew

APPENDIX A (Continued)

Numenius phaeopus – whimbrel
Phalaropus lobatus – red-necked phalarope
Tringa melanoleuca – greater yellowlegs
Tringa semipalmata – willet

***STRIGIDAE* – TYPICAL OWLS**
Athene cunicularia – burrowing owl
Bubo virginianus – great horned owl

***STURNIDAE* – STARLINGS**
Sturnus vulgaris – European starling

***THRESKIORNITHIDAE* – IBISES AND SPOONBILLS**
Plegadis chihi – white-faced ibis

***TROCHILIDAE* – HUMMINGBIRDS**
Archilochus alexandri – black-chinned hummingbird
Calypte anna – Anna's hummingbird
Calypte costae – Costa's hummingbird

***TROGLODYTIDAE* – WRENS**
Cistothorus palustris – marsh wren
Troglodytes aedon – house wren

***TYRANNIDAE* – TYRANT FLYCATCHERS**
Contopus sordidulus – western wood-pewee
Empidonax difficilis – Pacific-slope flycatcher
Empidonax traillii – willow flycatcher
Sayornis nigricans – black phoebe
Tyrannus verticalis – western kingbird
Tyrannus vociferans – Cassin's kingbird

***TYTONIDAE* – BARN OWLS**
Tyto alba – barn owl

If site name is different, what name(s) was used in the past?_____
If site was surveyed last year, did you survey the same general area this year? Yes ____ No ____ If no, summarize below.
Did you survey the same general area during each visit to this site this year? Yes X No ____ If no, summarize below.

Management Authority for Survey Area: Federal X Municipal/County ____ State ____ Tribal ____ Private ____
Name of Management Entity or Owner (e.g., Tonto National Forest) USFWS

Length of area surveyed: ___ ___ 3.2 (km)

Vegetation Characteristics: Check (only one) category that best describes the predominant tree/shrub foliar layer at this site:

_____ Native broadleaf plants (entirely or almost entirely, > 90% native)

_____ Mixed native and exotic plants (mostly native, 50 - 90% native)

_____ Mixed native and exotic plants (mostly exotic, 50 - 90% exotic)

X Exotic/introduced plants (entirely or almost entirely, > 90% exotic)

Identify the 2-3 predominant tree/shrub species in order of dominance. Use scientific names.
Tamarix sp.

Average height of canopy (Do not include a range): 4 (meters)

Attach the following: 1) copy of USGS quad/topographical map (REQUIRED) of survey area, outlining survey site and location of WIFL detections; 2) sketch or aerial photo showing site location, patch shape, survey route, location of any detected WIFLs or their nests; 3) photos of the interior of the patch, exterior of the patch, and overall site. Describe any unique habitat features in Comments.

Comments (such as start and end coordinates of survey area if changed among surveys, supplemental visits to sites, unique habitat features. Attach additional sheets if necessary.

Territory Summary Table. Provide the following information for each verified territory at your site.

Territory Number	All Dates Detected	UTM E	UTM N	Pair Confirmed? Y or N	Nest Found? Y or N	Description of How You Confirmed Territory and Breeding Status (e.g., vocalization type, pair interactions, nesting attempts, behavior)

Attach additional sheets if necessary

Willow Flycatcher (WIFL) Survey and Detection Form (revised April, 2010)

Site Name: Salton Sea SCH - New River A State: CA County: Imperial
USGS Quad Name: Westmorland West Elevation: -68 (meters)
Creek, River, or Lake Name: New River
Is copy of USGS map marked with survey area and WIFL sightings attached (as required)? *Yes* X *No* ____
Survey Coordinates: Start: E 115°41'41.177" N 33°8'0.609" UTM Datum: NAD83 (See instructions)
Stop: E 115°40'8.457" N 33°6'14.57" UTM Zone: 11
If survey coordinates changed between visits, enter coordinates for each survey in comments section on back of this page.
Fill in additional site information on back of this page*

Survey # Observer(s) (Full Name)	Date (m/d/y) Survey Time	Number of Adult WIFLs	Estimated Number of Pairs	Estimated Number of Territories	Nest(s) Found? Y or N If Yes, number of nests	Comments (e.g., bird behavior, evidence of pairs or breeding; potential threats [livestock, cowbirds, *Diorhabda* spp.]). If *Diorhabda* found, contact USFWS and State WIFL coordinator.	GPS Coordinates for WIFL Detections (this is an optional column for documenting individuals, pairs, or groups of birds found on each survey). Include additional sheets if necessary.			
Survey # 1 Observer(s): Brock Ortega	Date: 5/21/10 Start: 0515 Stop: 1100 Total hrs: 5.75	4	ϕ	ϕ	N		# Birds	Sex	UTM E	UTM N
Survey # 2 Observer(s): Brock Ortega	Date: 6/10/10 Start: 0500 Stop: 1115 Total hrs: 6.25	9	ϕ	ϕ	N		# Birds	Sex	UTM E	UTM N

Re: SW Willow Flycatcher Studies 2009
T&E Species Permit TE028605-2, Final Permit Report Deliverable

Ms. Marquez:

In fulfillment of SWCA Environmental Consultant's Federal Fish and Wildlife permit (TE028605-2) deliverable requirement with your department, please find enclosed on CD an annual report titled *Southwestern Willow Flycatcher Surveys, Color-banding and Nest Monitoring along the Lower Colorado River and Tributaries in Nevada, California, and Arizona,* 2009. This report details all of our Southwestern Willow Flycatcher studies conducted in California in 2009, and is presented in a site-by-site format to facilitate locating information of interest.

If you or your department requires any additional information, please do not hesitate contacting me directly: (928) 774-5500 ext. 201; tkoronkiewicz@swca.com.

Many thanks for your continuing support, sincerely,

Tom Koronkiewicz

T&E Species Permit TE028605-2, Final Report Deliverables

Ms. Marquez:

In fulfillment of SWCA Environmental Consultant's Federal Fish and Wildlife permit deliverable requirement with your department, please find enclosed on CDs annual reports titled *Southwestern Willow Flycatcher Surveys, Demography, and Ecology along the Lower Colorado River and Tributaries, 2009;* and, *Aerial Photographs of Southwestern Willow Flycatcher Nest and Territory Locations along the Virgin and Lower Colorado River Regions, 2009.* These reports detail all of our Southwestern Willow Flycatcher studies conducted in southern Nevada and California in 2009. All reports are presented in a site-by-site format to facilitate locating information of interest.

If you or your department requires any additional information, please do not hesitate contacting me directly: (928) 774-5500 ext. 201; tkoronkiewicz@swca.com.

EXECUTIVE SUMMARY

The Southwestern Willow Flycatcher (*Empidonax traillii extimus*), listed as federally endangered in 1995, breeds in dense, mesic riparian habitats at scattered, isolated sites in New Mexico, Arizona, southern California, southern Nevada, southern Utah, southwestern Colorado, and, at least historically, extreme northwestern Mexico. Historical breeding records and museum collections indicate a sizable population of Southwestern Willow Flycatchers may have existed along the extreme southern stretches of the lower Colorado River region. Factors contributing to the decline of flycatchers on the breeding grounds include loss, degradation, and/or fragmentation of riparian habitat; invasion of riparian habitat by nonnative plants; and brood parasitism by Brown-headed Cowbirds (*Molothrus ater*).

Willow flycatcher studies have been conducted along the Virgin and lower Colorado Rivers and tributaries annually since 1996, in compliance with requirements set forth by the U.S. Fish and Wildlife Service (USFWS) regarding U.S. Bureau of Reclamation (Reclamation) routine operations and maintenance along the lower Colorado River. Biological Assessments and the resulting Biological Opinions on operations and maintenance were prepared as steps to developing a Multi-Species Conservation Program (MSCP) for long-term endangered species compliance and management in the historical floodplain of the lower Colorado River (LCR). The LCR MSCP was signed in April 2005, and implementation of the program began in October 2005. The LCR MSCP calls for continued surveys and monitoring of willow flycatchers along the lower Colorado River. SWCA was contracted by Reclamation to continue surveys, monitoring, and demographic and ecological studies of the Southwestern Willow Flycatcher in suitable and/or historical riparian and wetland habitats throughout the Virgin and lower Colorado River regions in 2009.

Reclamation and USFWS completed a separate consultation on the potential effects to threatened and endangered species from implementation of surplus guidelines through 2016 and an annual change in the point of diversion for up to 400,000 acre-feet of California apportionment water for 75 years. The point of diversion, previously located below Parker Dam, would change to a point above Parker Dam. These changes in water regulation could cause a drop in floodplain groundwater levels of 1.55 feet (0.47 m) or less and have the potential to modify riparian habitats below Parker Dam. A Biological Opinion for Interim Surplus Criteria, Secretarial Implementation Agreements, and Conservation Measures was issued in January 2001 and required monitoring of 150.5 ha of existing, occupied Southwestern Willow Flycatcher habitat between Parker and Imperial Dams. In 2004, Reclamation biologists initiated studies of the microclimate within potentially affected areas. In 2005, these studies were continued and expanded by SWCA Environmental Consultants (SWCA) to address how the hydrological changes might affect riparian habitats along the Parker to Imperial reach.

Following the breeding season of 2008, USFWS and Reclamation initiated discussions regarding the declining number of willow flycatcher territories at Topock Marsh, the importance of the flycatcher population in the Topock area to flycatcher conservation along the LCR, and possible measures to enhance flycatcher habitat at Topock. A plan was developed to pump water into a portion of the flycatcher breeding habitat at Topock beginning in February or March and continuing into the flycatcher breeding season. Water delivery is anticipated to commence in 2010. Monitoring of vegetation, microclimate, and hydrologic condition in the target area was initiated in 2009 to obtain baseline conditions in the target area.

Breeding flycatchers have been documented annually in 1997–2008 at Pahranagat National Wildlife Refuge in southern Nevada. The primary breeding site at this study area was flooded by Upper Pahranagat Lake during each breeding season until 2008, when structural problems with a levee required draining the lake. USFWS retained SWCA to collect microclimate and vegetation data at Pahranagat in

2009 to compare conditions during inundated periods to the conditions in 2009 when the site was not inundated. Results of this study are presented in a separate chapter in this report.

Approximately 100 sites are included in the study of flycatchers along the Virgin and lower Colorado Rivers, but a portion of the sites are surveyed on a biennial basis rather than annually. In 2009, we completed presence/absence surveys and site descriptions at 69 sites in 15 study areas from the Pahranagat National Wildlife Refuge (NWR), Nevada, south to Yuma, Arizona. We also conducted more intensive studies at the seven study areas where territorial flycatchers were detected in 2009: Pahranagat NWR, Mesquite, Mormon Mesa, and Muddy River Nevada; and Littlefield, Topock Marsh, and Bill Williams River NWR, Arizona. At these study areas, we searched for nests in all areas occupied by territorial flycatchers, monitored willow flycatcher nests to document nest fate, brood parasitism, and causes of nest failure; color-banded and resighted as many willow flycatchers as possible to determine the breeding status of territorial flycatchers and document movement and recruitment; and measured characteristics of vegetation and microclimate in occupied territories and at old flycatcher nests in abandoned areas where we had collected similar data when the nest was active.

We used recorded broadcasts of willow flycatcher song and calls to elicit responses from willow flycatchers at 69 sites, ranging in size from <1 to 47 ha, along the Virgin and lower Colorado Rivers and tributaries between 15 May and 26 July 2009, following a 5-survey protocol. We detected willow flycatchers on at least one occasion at 41 of these sites. Breeding or resident flycatchers were detected at 19 sites within the Pahranagat NWR, Littlefield, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams study areas. South of Bill Williams, 44 willow flycatcher detections were recorded between 15 May and 16 June; no flycatcher detections were recorded at any of these sites after 16 June. Monitoring results suggest these flycatchers were not resident, breeding individuals and were most likely spring migrants.

We used targeted mist-net and passive netting techniques to capture and uniquely color-band adult and fledgling willow flycatchers at all survey sites where resident willow flycatchers were detected. Nestlings were banded between 8 and 10 days of age. We banded each willow flycatcher with a single, numbered U.S. federal aluminum band on one leg and one pin-striped, aluminum band on the other. We used binoculars to determine the identity of previously color-banded flycatchers by observing, from a distance, the unique color combinations on their legs.

We color-banded 17 new adult flycatchers and recaptured 8 individuals previously banded as adults. An additional 55 adults were identified to individual via resighting, while 10 individuals were resighted but did not have their color combinations confirmed. One individual had federal band on one leg and an injury on the other leg, and one adult had a duplicate color-band combination. We detected eight individuals identified as returning nestlings by the presence of a single federal band, with three (38%) identified to individual via recapture. Thirty-one adult flycatchers remained unbanded, and banding status was undetermined (i.e., we were unable to determine if these individuals were banded) for 19 adults. We banded 44 nestlings from 21 nests. We banded flycatchers opportunistically at Key Pittman Wildlife Management Area and St. George, capturing and color-banding six new adults and recapturing one returning nestling. Twelve nestlings from five nests were banded.

We recorded 76 territories at all monitored sites. Of these, 50 (66%) consisted of paired flycatchers and 22 (29%) consisted of unpaired individuals. In the remaining four territories (5%), a singing male was confirmed as resident and a second flycatcher, suspected to be a female, was detected for only a few days. Nine breeding males were polygynous, each pairing with two females. Three females mated consecutively with two different males.

Of the 75 resident, adult willow flycatchers identified to individual in 2008, 41 (55%) were identified in 2009; 1 (2%) was detected at a different study area from where it was last detected in 2008. We detected no within-year, between-study area movements in 2009.

Of the 73 juveniles banded at the monitored study areas in 2008, 12 (16%) were identified in 2009. Two additional flycatchers banded as nestlings in St. George in 2008 were identified in 2009. Four individuals originally banded as nestlings in previous years were identified for the first time in 2009. Of the 18 returning nestlings identified in 2009, 10 (56%) dispersed away from their natal study area. The median dispersal distance for all returning juvenile flycatchers in 2009 was 13.7 km.

We documented 72 willow flycatcher nesting attempts, 65 of which contained eggs and were used in calculating nest success and productivity. Twenty-three (35%) nests were successful and fledged young; 40 (62%) failed, and fate was unknown for 2 (3%). Mayfield survival probability ranged from 0.053 to 0.519 and was 0.368 for all sites combined. Depredation was the major cause of nest failure, accounting for 40% of all failed nests and 48% of nests that failed after flycatcher eggs were laid.

Sixteen of 56 nests (17%) with flycatcher eggs and known contents were brood parasitized by Brown-headed Cowbirds. Brood parasitism at all study areas ranged from 0 to 100% and was highest at Littlefield. We observed the seventh consecutive year of no brood parasitism at Pahranagat. Nests that contained flycatcher eggs and were brood parasitized were less likely to fledge flycatcher young than nests that were not parasitized.

At Littlefield, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams, we gathered data on vegetation and microclimate characteristics at one location for each of 56 territorial male flycatchers we identified, regardless of the length of time the male was resident and whether or not he obtained a mate. We delineated the following habitat types: 1) coyote willow, 2) tamarisk with coyote willow, 3) Goodding willow, 4) Goodding willow with tamarisk understory, 5) tamarisk with scattered Goodding willow, 6) tamarisk, and 7) cottonwood with mesquite. Coyote willow and Goodding willow are the only habitat types likely to be created at restoration areas, but we summarize vegetation and microclimate characteristics for all habitat types. Sample sizes in 2009 are likely too small to provide an accurate representation of the range and variance in vegetation and microclimate characteristics in each habitat type.

Territories within most vegetation types exhibited moist or inundated soil conditions throughout the breeding season. Several habitat types showed a general drying trend in soil conditions as the breeding season progressed. Daily maximum temperatures spanned a range of <10°C among habitat types, while daily minimum temperatures spanned <5°C. Vapor pressure increased through the end of July for all habitat types.

In addition to collecting vegetation and microclimate data at occupied territories, we investigated whether changes in vegetation and microclimate might have contributed to the abandonment of some areas by flycatchers. We identified areas at Mormon Mesa and Topock Marsh that had been occupied by nesting flycatchers in at least one previous year from 2003 to 2007 but were unoccupied in 2009, and we relocated old nests at which we had collected vegetation and microclimate information in the year the nest was active. We resampled microclimate and vegetation at these nests in 2009.

We had not noted dramatic, qualitative changes in vegetation in abandoned areas at Mormon Mesa or Topock Marsh. Vegetation data showed a decrease in the proportion of live stems 2.5–8 cm dbh at both study areas, which could reduce the suitability of the vegetation for flycatchers. The proportion of live stems >8 cm dbh increased at Topock, but this variable did not differ between the occupied year and 2009 at Mormon Mesa or when both study areas were combined. Canopy height increased at both Mormon Mesa and Topock between occupied and unoccupied periods, but this increase in canopy height is likely

the result of vegetation maturing over the years and probably did not contribute to abandonment of the area. Canopy closure increased at Mormon Mesa between occupied and unoccupied periods but showed a decreasing trend at Topock. Given that flycatchers typically nest in areas with very high canopy closure, it is unlikely that an increase in canopy closure would contribute to site abandonment. The apparent changes in canopy closure at both Mormon Mesa and Topock were small (<6%) and may be the result of observer variation.

Microclimate at old nests sites differed between occupied and unoccupied periods in at least one variable at both Mormon Mesa and Topock Marsh. At Mormon Mesa, nest sites had higher diurnal and nocturnal vapor pressure when they were occupied versus when they were abandoned. At Topock Marsh, nest sites had higher nocturnal vapor pressure when the nest was occupied. The differences in microclimate we observed between 2009 and the year the nest was occupied at both Topock and Mormon Mesa are likely the result of interannual climatic differences, as recorded at regional weather stations, and not the result of localized changes at the nest sites.

In 2005, we selected 11 sites between Parker and Imperial Dams for inclusion in the habitat monitoring study addressing how changes in water transfer actions might affect riparian habitat. We also selected two control sites above Parker Dam and two below Imperial Dam. At each site we installed 3–5 temperature/humidity data loggers and one groundwater observation well (piezometer). All logger and piezometer locations selected in 2005 were retained in 2006. In August 2006, we installed a piezometer and two temperature/humidity data loggers within occupied flycatcher habitat at Topock Marsh. Two loggers and one piezometer were damaged or destroyed in a fire in December 2006 and were replaced in 2007, and one piezometer that was destroyed by a bulldozer in 2007 was replaced in 2008. At sites that were surveyed for flycatchers in 2009, soil moisture measurements were collected at each data logger location during each of five flycatcher surveys between 15 May and 25 July. At sites that were not surveyed in 2009, soil moisture measurements were collected at the beginning and end of the survey season. Vegetation measurements were also collected at each data logger location after surveys were completed. We used data from piezometers that were located within the woody, riparian vegetation to evaluate whether the evapotranspiration signature in June–August changed over time from 2005 to present. We also compared microclimate characteristics at the habitat monitoring sites to those found within flycatcher territories at Topock Marsh.

Several microclimatic variables at the combined habitat monitoring sites differed significantly from those at Topock Marsh in 2009, with Topock being cooler and more humid than the habitat monitoring sites. Comparison of microclimate variables at the habitat monitoring sites to those at within flycatcher territories at Topock Marsh in each year from 2005 to 2009 have shown that the habitat monitoring sites consistently have warmer temperatures, greater daily temperature range, and lower humidity than occupied territories.

Comparisons of microclimate characteristics among years in 2005–2009 at the habitat monitoring sites indicated hotter and more humid conditions in 2006 than in the other years and cooler conditions in 2009. These interannual changes were similar between test and control sites, suggesting that these changes were regional, rather than being influenced by local conditions. The interannual changes in soil moisture in 2005–2006 and 2007–2008 were not similar between test and control sites, with soil moisture declining more sharply at the control sites. This suggests that local conditions, in addition to regional climate, may have influenced soil moisture. Mean daily temperature range and mean maximum diurnal temperature were higher at test sites but lower at control sites in 2008 versus 2007. These metrics decreased sharply in 2009 at both test and control sites, presumably in response to the unusually cool climate conditions during portions of summer 2009. Thus, there have not been any consistent patterns in the changes in microclimate characteristics at test versus control sites that could be attributed to changes in river flows.

We noted between-year differences at the habitat monitoring sites for several vegetation variables. The only variables that exhibited a consistent change across time were percentage of live stems <2.5 cm dbh, which declined steadily from 2005 to 2009, and percentage of live stems 2.5–8 cm dbh, which was lower in 2008 and 2009 than in the three preceding years. Woody ground cover was the only variable for which there was a significant interaction with location, meaning the changes in all the other variables between years among test sites was not significantly different from the change at control sites. Average woody ground cover increased at control plots between 2005 and 2006 and then decreased in 2007, while it did not change at test plots across those years.

There was a between-year difference in live vegetation in the fourth meter interval above the ground and between-year differences for the first, second, third, and fourth meter intervals above the ground for dead vegetation. In all four intervals, density of dead vegetation was higher in 2008 than in 2007. There was a significant interaction between live vertical foliage density and location (test vs. control sites) for the fourth meter interval, but there was no clear pattern, with density generally increasing at control plots in years it decreased at test plots, and vice versa. There was also a significant interaction between dead vertical foliage density and location for the first meter interval, with the density of dead vegetation increasing more in 2007 and 2008 at control plots relative to test plots. The percentage of live vegetation in each meter interval differed between years only in the fourth meter interval; in this case, the live percentage was lower in 2008 than in 2007.

It has become apparent, after measuring the same vegetation plots for several consecutive years, that stem counts in very dense vegetation are inherently inaccurate and imprecise and can vary widely from year to year when there has likely been no appreciable change in stem density. Given the difficulties in producing repeatable stem counts, absolute stem counts are likely not a suitable metric for detecting subtle changes in vegetation. The proportion of live stems may provide a more sensitive metric by which to detect change; the accuracy of this measure depends only on each observer counting live stems in a manner consistent with how s/he counts dead stems. Similarly, the proportion of live vertical foliage is likely to provide a more sensitive measure of changes in vegetation than do the absolute vertical foliage counts. The detection of changes in vegetation as the result of the diversion of water at Parker rather than Imperial Dam is further hampered by the complete lack of vegetation measurements prior to the beginning of the diversion in 2002. Vegetation measurements did not commence until 2005, by which time it is possible that some changes in vegetation, particularly in sensitive species such as coyote willow, had already occurred.

Daily, weekly, and seasonal cycles in groundwater levels were apparent. Groundwater levels drop during afternoon hours when evapotranspiration is high and on the weekends when water releases from Parker Dam decline. The seasonal cycle in groundwater levels mirrors the seasonal fluctuation in river flow.

Of the 10 piezometers that were within the woody, riparian vegetation, only 6 yielded usable evapotranspiration signature data over multiple years. Inspection of the hydrographs revealed that intraday changes in groundwater level were influenced strongly by the cyclic changes in river water levels associated with dam releases. These sharp rises and declines in the river level overwhelmed the evapotranspiration signature, and data from the piezometers along the river could not be used to assess changes in evapotranspiration signature over time. Further analysis of evapotranspiration data was restricted to the piezometer at Topock Marsh.

The evapotranspiration signature was strongly, directly correlated with depth to groundwater and weakly, directly correlated to temperature during May–August, 2007 and 2009. However, temperature was also correlated with depth to groundwater, because both increased over the May–August period each year. The evapotranspiration signature at Topock Marsh was directly related to depth to groundwater, rather than showing the inverse relationship demonstrated in the literature. The magnitude of the

evapotranspiration signature at Topock appears to be driven by local groundwater hydraulics, and changes in the evapotranspiration signature over time cannot by used as a proxy for vegetation change.

We measured baseline vegetation, microclimate, and surface hydrology conditions in an area of Topock Marsh that is scheduled for delivery of supplemental surface water in 2010. We stratified the site into use (occupied by flycatchers) and non-use (unoccupied by flycatchers) areas, as observed in 2003–2008. We deployed temperature/humidity data loggers within both the use and non-use areas, collected soil moisture measurement biweekly at each logger location, mapped surface water throughout the area on a weekly basis, and collected vegetation data at each logger location at the end of flycatcher breeding season. The percentage of the area that was inundated rose rapidly in late March and early April to a high of almost 45% and then declined just as rapidly in May. By early June, <5% of the site had surface water. Vegetation was primarily tamarisk and had high canopy closure. The densest live foliage occurred above average nest height, and the densest dead vegetation occurred within 3 m of the ground. Soil conditions became progressively drier throughout the season for both the use and non-use areas, while vapor pressure values showed the typical rise seen in July with the onset of summer monsoons. Conditions documented in 2009 will be compared to those documented in 2010 when additional surface water is delivered to the site.

The main flycatcher breeding area at Pahranagat National Wildlife Refuge was inundated annually during the flycatcher breeding seasons of 1997–2007, with up to 1 m of water recorded under the vegetation in mid-May. Major structural problems with the levee that impounds Upper Pahranagat Lake resulted in the site being dry during the breeding seasons of 2008 and 2009. We collected microclimate and vegetation data within the site during 2009 and compared these measurements to vegetation and microclimate data collected within flycatcher territories at the site from 2005 to 2007. The only vegetation variable that differed between the inundated and non-inundated periods was the percentage of the foliage that consisted of native species. This difference is entirely attributable to the development in 2009 of herbaceous ground cover consisting partially of a non-native *Chenopodium* species and does not reflect any change in the woody vegetation.

Microclimate conditions differed between the inundated and non-inundated periods by soil moisture and diurnal and nocturnal vapor pressure being higher during the inundated period. Without humidity data from a nearby weather station, it is impossible to determine if the difference in humidity is attributable to changes in water levels or simply lower regional humidity in 2009. We had expected that inundated conditions might serve to moderate daily temperatures, but the data showed a higher maximum temperature and lower minimum temperature during the inundated period. These differences could not be accounted for by between-year differences in regional climate, with the Caliente weather station showing no between-year differences for either maximum or minimum temperature.

Chapter 2

PRESENCE/ABSENCE SURVEYS AND SITE DESCRIPTIONS

INTRODUCTION

Broadcasts of recorded conspecific vocalizations are useful in eliciting responses from nearby willow flycatchers, and multiple broadcast surveys conducted throughout the breeding season are the standard technique for determining the presence or absence of ***E. t. extimus*** (Sogge et al. 1997). According to Sogge et al. (1997) and USFWS (2002), willow flycatchers detected between approximately 15 June and 20 July in the breeding range of ***E. t. extimus*** probably belong to the southwestern subspecies. However, because northbound individuals of all western subspecies of the willow flycatcher migrate through areas where ***E. t. extimus*** are actively nesting, and southbound migrants occur where ***E. t. extimus*** are still breeding (Sogge et al. 1997, USFWS 2002), field confirmation of the southwestern subspecies is problematic.[1] For example, the northwestern ***E. t. brewsteri***, far more numerous than ***E. t. extimus***, has been documented migrating north in southern California as late as 20 June (Garrett and Dunn 1981 as cited in Unitt 1987), and Phillips et al. (1964 as cited in Unitt 1987) documented ***E. t. brewsteri*** collected in southern Arizona on 23 June. An understanding of willow flycatcher migration ecology in combination with multiple broadcast surveys conducted throughout the breeding season is therefore needed to assess the presence and residency of Southwestern Willow Flycatchers.

Migration routes used by ***E. t. extimus*** are not well documented, though more is known of northbound migration in spring than the southbound migration in fall because flycatchers are more vocal in spring and can therefore be distinguished from other ***Empidonax*** species. During northbound migration, all subspecies of willow flycatchers use riparian habitats similar to breeding habitat along major river drainages in the Southwest such as the Rio Grande (Finch and Kelly 1999), Colorado River (McKernan and Braden 1999), San Juan River (Johnson and Sogge 1997), and the Green River (M. Johnson unpubl. data). Although migrating willow flycatchers may favor young, native willow habitats (Yong and Finch 1997), migrants are also found in both spring and fall in a variety of habitats that are unsuitable for breeding. These migration stopover habitats, even though not used for breeding, are likely important for both reproduction and survival. For most long-distance Neotropical migrant passerines, migration stopover habitats are needed to replenish energy reserves to continue northbound or southbound migration.

In 2009, we completed multiple broadcast surveys at sites in 15 study areas[2] along the LCR and its tributaries to detect both migrant and resident willow flycatchers (Figure 2.1).

Special Concern Species

The Yuma Clapper Rail (***Rallus longirostris yumanensis***) is listed as federally endangered by the USFWS, and the Yellow-billed Cuckoo (***Coccyzus americanus occidentalis***) is a candidate for federal listing. Both species occur along the LCR and its tributaries and are of concern to managing agencies. Nine additional avian species [California Black Rail (***Laterallus jamaicensis coturniculus***), Western Least Bittern (***Ixobrychus exilis***), Elf Owl (***Micrathene whitneyi***), Gila Woodpecker (***Melanerpes uropygialis***), Gilded Northern Flicker (***Colaptes auratus chrysoides***), Vermilion Flycatcher (***Pyrocephalus rubinus***),

[1] Throughout this document, the terms "flycatcher" and "willow flycatcher" refer to ***E. t. extimus*** when individuals are confirmed as residents. For individuals for which residency is undetermined, subspecies is unknown.

[2] Study areas consist of 1–18 survey sites that are grouped geographically (see Table 2.2).

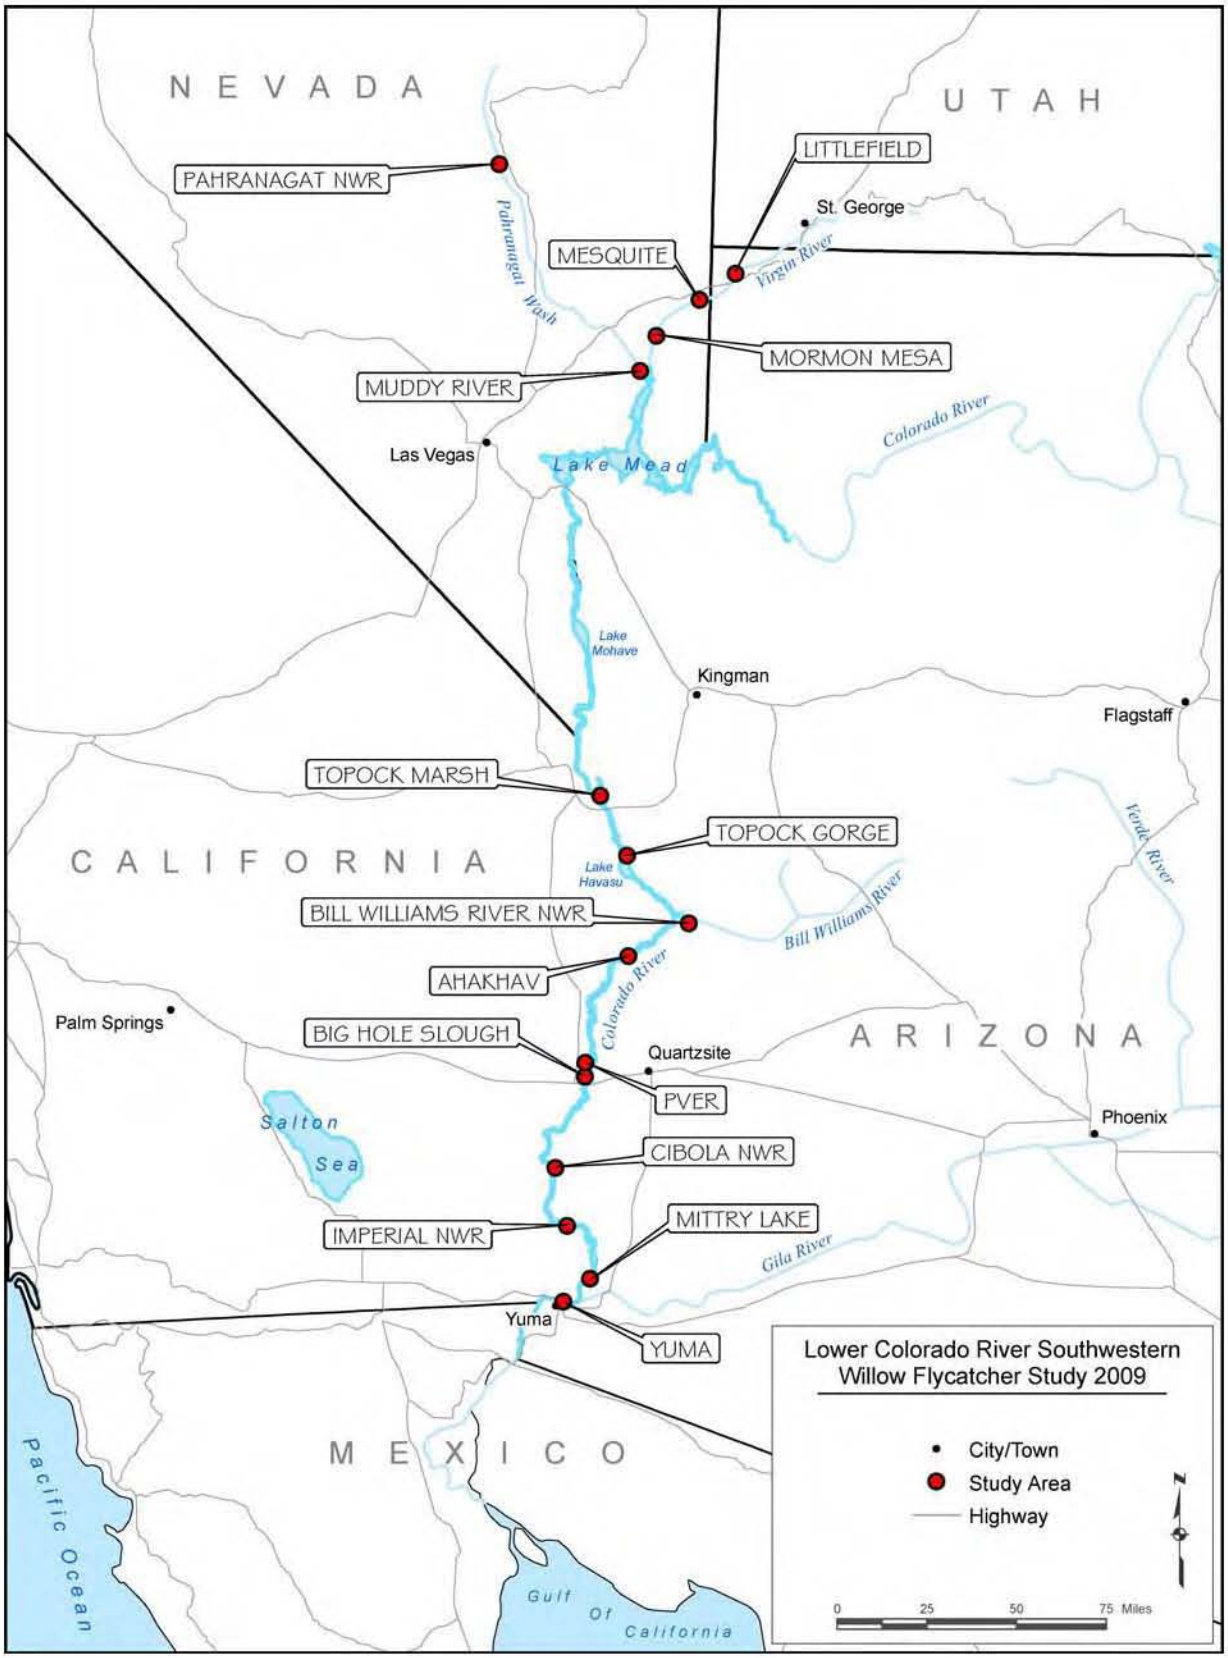

Figure 2.1. Locations of Southwestern Willow Flycatcher study areas along the lower Colorado River and tributaries, 2009. (Note, study area labels represent the approximate center of multiple sites within that region; see Table 2.2)

Arizona Bell's Vireo (*Vireo bellii arizonae*), Yellow Warbler (*Dendroica petechia*), and Summer Tanager (*Piranga rubra*)] are considered to be special-concern species under the LCR MSCP. The Yellow-breasted Chat (*Icteria virens*) is also considered a special concern species in California. We did not survey specifically for these species but recorded all incidental detections.

METHODS

Site Selection

Survey sites were selected based on locations surveyed during previous years of willow flycatcher studies on the LCR (McKernan 1997; McKernan and Braden 1998, 1999, 2001a, 2001b, 2002; McLeod et al. 2008, McLeod and Koronkiewicz 2009) and reconnaissance by helicopter and on foot prior to the start of the 2009 survey period. Sites consisting of mature native or exotic woody riparian vegetation with high canopy closure (>50%) and standing water or saturated soil under or adjacent to the vegetation were considered the most suitable habitats for flycatchers. Early successional stands of young riparian vegetation >3 m in height in proximity to surface water or saturated soil were also considered potentially suitable flycatcher habitat. Riparian vegetation contiguous with suitable habitat was often included as part of survey areas. Reclamation biologist Theresa Olson guided and approved site selection. For sites surveyed in previous years, we retained original site names.

In 2008 we implemented a biennial survey schedule at selected sites in study areas where resident flycatchers had not been documented in the previous 10 years of surveys. Sites were selected for biennial surveys based on the absence of damp or wet soils within the site and/or the relative absence of dense vegetation that might provide suitable nesting habitat for flycatchers. After the 2008 survey season, we revised the survey schedule based on conditions observed in the field and added several sites at Bill Williams to the biennial schedule. These sites were ones at which no resident flycatchers had been detected since 2003. The proposed schedule at the beginning of the 2009 survey season is given in Table 2.1 and may be further revised based on conditions observed during 2009.

Table 2.1. Proposed Survey Schedule for Selected Sites

Study Area[1]	Site	Habitat Comments	Proposed Survey Schedule		
			Annual	2008, 2010, 2012	2009, 2011
TOGO	Pulpit Rock	Tiny. Wet soil adjacent to river; upland edge dry.			X
	Picture Rock	Wet soil adjacent to river, interior dry.			X
	Blankenship Bend North	Stand of willow adjacent to marsh.	X		
	Blankenship Bend South	Mosaic of cattail, bulrush, willow. Areas with water under vegetation.	X		
	Havasu NE	Mature vegetation; interior of site is completely dry, no water beneath the vegetation.		X	
BIWI	Site #2	Mature mixed-native vegetation; dry soils and extensive deadfall within the site; bordered by an arm of Lake Havasu.		X	
	Site #11	Mature mixed-native vegetation; dry soils and extensive deadfall within the site; bordered by an arm of Lake Havasu.		X	

Table 2.1. Proposed Survey Schedule for Selected Sites (Continued)

Study Area[1]	Site	Habitat Comments	Proposed Survey Schedule		
			Annual	2008, 2010, 2012	2009, 2011
BIWI	Mineral Wash	Mixed-native vegetation; sparse canopy closure; dry soil underneath the vegetation; water only within river channels.		X	
	Beaver Pond	Mixed-native vegetation; sparse canopy closure; dry soil underneath the vegetation; water only within river channels.		X	
	Site #8	Mixed-native vegetation; sparse canopy closure; dry soil underneath the vegetation; water only within the river channel.		X	
PVER	PVER Phase 2	Restoration area.	X		
BIHO	Big Hole Slough	Marshy, new willows coming in.	X		
EHRE	Ehrenberg	Emergent cottonwood and Goodding willow; understory primarily arrowweed and ***Baccharis*** sp.; formerly contained a dense stand of coyote willow but these willows have all died.		X	
CIBO	CVCA Phase 1	Restoration area.	X		
	CVCA Phase 3	Restoration area.	X		
	Cibola Nature Trail	Generally dry and sparse, restoration area. Habitat improvements taking place, may improve.	X		
	Cibola Island	Narrow, linear site; patches of dense Goodding willow adjacent to marsh.	X		
	Cibola Site 2	No dense canopy. Mostly tamarisk with some emergent willow. Cattail marshes in parts of the site, but dry soil under the tamarisk.			X
	Cibola Site 1	No dense canopy. Mostly tamarisk with some emergent willow. Cattail marshes in parts of the site, but dry soil under the tamarisk.			X
	Hart Mine Marsh	Mostly tamarisk, with linear stretches of marsh vegetation. Dry soil under the tamarisk.			X
	Three Fingers Lake	Very dry and hot in interior, vegetation short.		X	
	Cibola Lake #1 (North)	Patchy vegetation, hot and dry in interior.		X	
	Cibola Lake #2 (East)	Patchy vegetation, hot and dry in interior.			X
	Cibola Lake #3 (West)	Patchy vegetation, hot and dry in interior.		X	
	Walker Lake	Tamarisk with emergent willows; water under vegetation along lake edge.	X		
IMPE	Paradise	Some big willows with tamarisk understory, sometimes has water in marshes.	X		
	Hoge Ranch	Mosaic of tamarisk, willow, and marshes. Sometimes wet.	X		

Table 2.1. Proposed Survey Schedule for Selected Sites (Continued)

Study Area[1]	Site	Habitat Comments	Proposed Survey Schedule		
			Annual	2008, 2010, 2012	2009, 2011
IMPE	Adobe Lake	Perched above river, very dry, dense tamarisk with many dead branches in understory.		X	
	Rattlesnake	Dense willows, wet soils.	X		
	Milemarker 65	Very narrow strip (<50m) of tamarisk adjacent to bulrush marsh. Understory of ***Phragmites*** creates extremely dense vegetation within 3 m of ground.			X
	Clear Lake/The Alley	Mature tamarisk, very dense understory. Very dry except immediately next to backwater channel.		X	
	Nursery NW	Dense tamarisk interspersed with marsh areas.	X		
	Imperial Nursery	Plantation. No understory.		X	
	Ferguson Lake	Mix of willow and tamarisk with water under vegetation on west side of site. East side is dry and scrubby.	X		
	Ferguson Wash	Mature tamarisk with emergent willow. Very dry in interior of site. Borders backwater channel and Ferguson Lake. Moist soils only along channel edge.		X	
	Great Blue Heron	Goodding willow overstory, tamarisk understory; moist soils in parts of the site.	X		
	Powerline	Very small, stringer of trees around cattail marsh that sometimes contains water. Sparse canopy.			X
	Martinez Lake	Scattered willows, tamarisk and arrowweed understory, sparse canopy closure.			X
MITT	Mittry West	Willow overstory, tamarisk understory, 80% canopy closure, sometimes wet.	X		
	Mittry South	Monotypic tamarisk, lots of deadfall. Interior is dry. Adjacent to lake.		X	
YUMA	Gila Confluence North	Patchy. A few small stands of mature willows around cattail marshes. Marshes sometimes contain water. Half of site burned in 2006. Overall canopy closure 50%.		X	
	Gila River Site #2	Cottonwood/willow overstory, tamarisk and arrowweed understory, dry soils in interior, canopy closure 50%.			X
	Fortuna Site #1	Narrow (30m) strip of cottonwood/willow. Patchy understory of tamarisk and arrowweed on periphery, no understory within cottonwood/willow. Interior is dry.			X
	Fortuna North	Mature tamarisk, 80% canopy closure. Interior very dry. Adjacent to Gila River.			X
	Morelos Dam	Recovering from fire, canopy closure less than 50%, widely spaced willow and cottonwood, dense patch of tamarisk on northern end of site.			X

[1] TOGO = Topock Gorge, BIWI = Bill Williams River NWR, PVER = Palo Verde Ecological Reserve, BIHO = Big Hole Slough, EHRE = Ehrenberg, CIBO = Cibola NWR, IMPE = Imperial NWR, MITT = Mittry Lake, YUMA = Yuma.

We provided field personnel with high-resolution aerial photographs of all selected survey sites. The photographs were overlain with a UTM grid (NAD 83) and an outline of the proposed survey area. The boundaries of all survey sites were refined to include potential flycatcher habitat actually present. New boundaries were delineated on the aerial photographs based on UTM coordinates obtained in the field. All UTM coordinates were obtained using a Garmin Rino 110 GPS unit and were in NAD 83 to comply with Federal Geographic Data Committee standards.

Additional Site Evaluation

During the survey season, we conducted on-the-ground habitat reconnaissance and evaluation to locate additional potentially suitable willow flycatcher habitat and to reevaluate areas we had visited in previous years and had noted as having the potential to become suitable habitat. Field personnel were provided high-resolution aerial photographs overlain with a UTM grid to aide with navigation and the identification of potentially suitable flycatcher habitat. We focused habitat reconnaissance and evaluation in areas that contained or were adjacent to standing water or saturated soils, and that had vegetation characteristics similar to that of flycatcher breeding sites (i.e., dense vegetation within 2–4 m of the ground and high canopy closure). Broadcast surveys were conducted opportunistically during ground reconnaissance. Field personnel formulated qualitative site descriptions of all evaluated areas.

Broadcast Surveys

To elicit responses from nearby willow flycatchers, we broadcast conspecific vocalizations previously recorded throughout the Southwest from 1996 to 1998. All flycatcher surveys were conducted according to methods described in Sogge et al. (1997), and we followed a 5-survey protocol, as recommended by the U.S. Fish and Wildlife Service (USFWS 2000). We completed at least one survey between 15 and 31 May, at least one survey between 1 and 15 June, and three additional surveys between 16 June and 25 July. Surveys were separated by a minimum of five days whenever logistically possible. Field personnel surveyed within the habitat wherever possible, using a portable CD or MP3 player (various models were used) coupled to a Radio Shack 277-1008C mini amplified speaker. Surveyors stopped every 30–40 m and broadcast willow flycatcher primary song (***fitz-bew***) and calls (***breets***). Field personnel watched for flycatchers and listened for vocal responses for approximately one to two minutes before proceeding to the next survey station. Wherever territorial flycatchers were detected, broadcast surveys were discontinued within a radius of 50 m of territories, and territory and nest monitoring commenced (see Chapter 4). If an unidentified ***Empidonax*** flycatcher was observed but did not respond with song to the initial broadcast, we broadcast other conspecific vocalizations including ***creets/breets***, ***wee-oos***, ***whitts***, ***churr/kitters***, and a set of interaction calls given by a mated pair of flycatchers (per Lynn et al. 2003). These calls are frequently effective in eliciting a ***fitz-bew*** song, thereby enabling surveyors to positively identify willow flycatchers. To produce a spatial representation of all survey areas, field personnel recorded survey start and stop UTM coordinates as well as the UTM coordinates of intermediate survey points. Observers recorded start and stop times and the location(s) and behavior of all willow flycatchers detected (see survey form, Appendix A). Field personnel also recorded the presence of Brown-headed Cowbirds (hereafter cowbirds) and livestock, as requested by the Arizona Game and Fish Department. Cowbirds may affect flycatcher populations by decreasing flycatcher productivity (see Chapter 4), while livestock may substantially alter the vegetation in an area (USFWS 2002).

Site Description

Because vegetation structure and hydrology within riparian habitats are seasonally dynamic, field personnel completed site description forms (Appendix A) for each survey site at least three times throughout the survey season: early season (mid-May), mid-season (mid-June), and late season (mid-July). Vegetation composition (native vs. exotic) at survey sites followed the definitions of Sogge et al. (1997) and the Southwestern Willow Flycatcher Range-wide Database. Vegetation composition was defined as (1) native: >90% of the vegetation at a site was native; (2) exotic: >90% of the vegetation at a site was exotic/introduced; (3) mixed-native: 50 to 90% of the vegetation at a site was native; or (4) mixed-exotic: 50 to 90% of the vegetation at a site was exotic/introduced. Information from site description forms was used in conjunction with habitat photographs and comments in field notebooks and on survey forms to formulate qualitative site descriptions.

RESULTS

Field personnel spent 661.2 observer-hours conducting willow flycatcher broadcast surveys at 69 sites along the Virgin and lower Colorado Rivers and tributaries.[3] Willow flycatcher survey results are summarized in Table 2.2 and are presented below along with site descriptions. Details of occupancy, pairing, color-banding, and breeding are presented in Chapters 3 and 4. The boundaries of survey sites and occupancy in 2009 are shown on orthophotos in Appendix B, along with historically occupied habitat.[4] Each site that was not occupied by territorial flycatchers was formally surveyed five times. Field personnel spent an additional 45.5 observer-hours completing habitat reconnaissance and evaluation and opportunistic surveys. The results of reconnaissance for each study area are presented below following the results for the regularly surveyed sites. Because subspecies identification of willow flycatchers detected between approximately 15 June and 20 July in the breeding range of ***E. t. extimus*** is problematic (Sogge et al. 1997, USFWS 2002), flycatcher detections after 15 June at sites where breeding or residency was not confirmed are summarized in Table 2.3. Yellow-billed Cuckoo and Yuma Clapper Rail detections are listed in Tables 2.4 and 2.5, respectively, and overall numbers of detections of all special concern species are listed in Appendix C. Hydrologic characteristics of each site are summarized in Table 2.6.

Table 2.2. Willow Flycatcher Detections at Survey Sites along the Virgin and Colorado Rivers and Tributaries, 2009*

Study Area[1]	Survey Site	Area (ha)	Number Detected (Date(s) of Detection)[2,3]
PAHR	North	4.6	23 (6 May–13 Aug)
	West	1.5	ND
	MAPS	2.7	ND
	South	2.5	1 (22 Jun)
LIFI	Poles	4.7	5 (1 Jun–26 Jul)
MESQ	East	4.4	ND
	West	11.5	21 (10 May–13 Aug)

[3] We started the survey season with 70 sites scheduled for surveys in 2009. One site had been bulldozed prior to the start of the survey season and was not surveyed. We discontinued surveys at two additional sites, one because of poor habitat quality and another because a fire destroyed vegetation in most of the site.

[4] As per Reclamation (1999), we defined occupied Southwestern Willow Flycatcher habitat as patches of vegetation that are similar to and contiguous with areas where willow flycatchers were detected after 15 June.

* Values are given for each site as recorded in mid-May, mid-June, and mid-July.

[1] PAHR = Pahranagat NWR, LIFI = Littlefield, MESQ = Mesquite West, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, TOGO = Topock Gorge, AHAK = Ahakhav Tribal Preserve, BIWI = Bill Williams River NWR, PVER = Palo Verde Ecological Reserve, BIHO = Big Hole Slough, CIBO = Cibola NWR, IMPE = Imperial NWR, MITT = Mittry Lake, YUMA = Yuma.

[2] -- = Hydrologic information not recorded.

[3] Percent of site with saturated soil does not include inundated areas.

[4] Site bordered by a river, lake, or pond.

[5] Saturated soil or water was present only in pig wallows.

[6] Site borders marsh.

[7] Site is irrigated as part of restoration efforts; amount of standing water highly variable throughout survey season.

Pahranagat National Wildlife Refuge, Nevada

Pahranagat National Wildlife Refuge consists of a series of lakes and marshes in Pahranagat Valley approximately 150 km north of Las Vegas, Nevada. Patches of primarily native vegetation exist at the inflow and outflow of Upper Pahranagat Lake. Prior to the 2008 survey season, the majority of the riparian vegetation along the north side of the upper lake (Pahranagat North) was inundated annually with

up to 1 m of water, with the highest water levels occurring in May. Major structural problems with the levee that impounds the upper lake resulted in the upper lake being drained in early 2008, and the riparian vegetation at the north end of the lake was not flooded during the 2008 or 2009 breeding seasons.

Pahranagat North

Area: 4.6 ha Elevation: 1,026 m

Pahranagat North is a stand of large-diameter Goodding willow (*Salix gooddingii*) at the inflow of Upper Pahranagat Lake. Fremont cottonwood (*Populus fremontii*; hereafter cottonwood) lines the northern, upland edge of the site and extends in narrow stringers around the edge of the lakebed. Canopy height within the patch is 15–18 m, and canopy closure is approximately 70%, similar to that recorded in 2008. Canopy closure from 2003 to 2007 was >90%. Reduced canopy closure in 2008–2009 occurred mostly in the northeastern section of the site, where many of the large trees are now dead or dying. During the survey season, standing water and saturated soils were present only in an inflow channel that runs along the northern side of the site and drains into the lakebed at the southeastern corner of the site. The water channel is vegetated with bulrush (*Schoenoplectus* sp.) where it enters the lakebed. Saturated soils were also present within patches of bulrush that border the southern edges of the site.

We detected 20 breeding willow flycatchers, as well as 1 resident, unpaired male. In addition to resident adults, we detected two individuals for which residency and breeding status could not be confirmed. Areas of Pahranagat North not known to be occupied by willow flycatchers were surveyed five times, totaling 6.1 observer-hours. The site lies immediately adjacent to a cattle pasture, but livestock have access only to the cottonwood stringer on the northwestern corner of the lake, which is separated from the survey site by a fence. Cowbirds were detected during one survey and were detected regularly during nest monitoring activities.

Pahranagat West

Area: 1.5 ha Elevation: 1,026 m

This native site consists of a stringer of cottonwood, one to three trees wide and 20 m in height, on the western edge of Upper Pahranagat Lake. The site has no significant understory vegetation, and canopy closure varies from <50 to 80%. The eastern edge of the site is vegetated with bulrush, which extends into the lakebed to the east. During the survey season, the interior of the site was dry, but surface water was present nearby in the lakebed.

We detected no willow flycatchers. We surveyed the site five times, totaling 3.2 observer-hours. No cowbirds were detected, and there was no sign of livestock use.

Pahranagat MAPS

Area: 2.7 ha Elevation: 1,026 m

Pahranagat MAPS is a stringer of cottonwood on the western edge of the bed of Upper Pahranagat Lake. Canopy height is 15–20 m, and canopy closure is approximately 60%. There is very little woody vegetation in the understory. Cattail (*Typha* sp.) and bulrush line the eastern edge of the tree line and extend into the lakebed; much of this vegetation is dead. The site was dry throughout the survey season, with the nearest water or saturated soil being at least 20 and up to 200 m away in the lakebed.

No willow flycatchers were detected. We surveyed the site five times, totaling 3.5 observer-hours. Cowbird were detected on two surveys, and there was no evidence of livestock use.

Pahranagat South

Area: 2.5 ha Elevation: 1,023 m

Pahranagat South consists of a relatively small stringer of Goodding willow, coyote willow (***Salix exigua***), and cottonwood lining a human-made channel that carries the outflow from Upper Pahranagat Lake. The cottonwoods reach approximately 20 m in height, while the willows are generally less than 10 m. In 2005, we noted that dense coyote willow was increasing on the western side of the site; this area of willow had very sparse canopy in 2006 and 2007, and the coyote willow was almost completely dead by 2008. The site is bordered to the west by an open marsh and to the east by upland scrub. Tamarisk (***Tamarix*** spp.) and Russian olive (***Elaeagnus angustifolia***) form a sparse understory. Overall canopy closure at this site is approximately 50%. The channel held water during site visits in May and June but was dry in mid-July.

We detected one willow flycatcher, for which residency and breeding status could not be confirmed, on 22 June after receiving a report from field personnel from an unrelated project that a flycatcher had been detected at the site. The flycatcher was not detected on any of three subsequent territory monitoring visits or on any of the surveys. We surveyed the site five times, totaling 2.8 observer-hours. Cowbirds were detected during two surveys, and no sign of livestock was observed.

Littlefield, Arizona

In 2007, our survey and monitoring activities focused on an area along Beaver Dam Wash immediately upstream of the Highway 91 Bridge. We expanded the survey area in 2008 to include young Goodding and coyote willow stringers downstream of the bridge and expanded the survey area even farther downstream in 2009.

Littlefield Poles

Area: 4.7 ha Elevation: 565 m

Littlefield Poles consists of primarily native vegetation located on Beaver Dam Wash, immediately upstream and downstream of the Highway 91 Bridge. Vegetation upstream of the bridge consists of a scattered overstory of cottonwood averaging 25 m in height. Cottonwood and Goodding willow averaging 10 m in height are present below the overstory but do not form a continuous canopy. Lower strata vegetation approximately 6 m in height consists of coyote willow, tamarisk, and some Russian olive. Dense stands of coyote willow border the southern edge of the patch, along the stream. Downstream of the bridge, young stringers of Goodding and coyote willow reach 5 m in height and form linear patches 10–15 m wide on the edges of multiple stream channels. Larger Goodding willow is present along the southwestern edge of the site on the edge of a golf course, and a dense patch of Goodding willow is present on the northern edge of the downstream end of the site. The downstream end of the site borders a cattail marsh. Canopy closure in the densest areas of Goodding and coyote willow is >90%, though overall canopy closure ranges from 50 to 70%. Surface water was present in stream channels and in the cattail marsh throughout the survey season.

We detected three breeding willow flycatchers; one resident, unpaired male; and one willow flycatcher for which residency could not be confirmed. Portions of the site not known to be occupied by flycatchers

were surveyed five times, totaling 14.5 observer-hours. Cowbirds were detected on all surveys, and cattle scat and trails were observed in the site.

Mesquite, Nevada

The Mesquite study area is in the floodplain of the Virgin River near Mesquite and Bunkerville, Nevada. The entire area experience flooding, and some areas were scoured, during the 2004–2005 winter floods.

Mesquite East

Area: 4.4 ha Elevation: 468 m

This mixed-native site lies on several terraces within the floodplain of the Virgin River in Mesquite, Nevada. Vegetation on the lowest terrace, on the northern edge of the site adjacent to the river, consists of cottonwood and Goodding willow generally less than 10 m in height. The central portion of the site lies on a slightly higher terrace and is vegetated entirely by dense tamarisk 7–8 m in height with canopy closure around 80%. The uppermost terrace is vegetated with Goodding willow and a few cottonwood 18–25 m in height and an understory of dense clumps of coyote willow about 8 m in height. Canopy closure on this terrace varies from 50% in the cottonwood/Goodding willow areas to over 90% in the coyote willow clumps. The western half of the upper terrace burned over the 2004–2005 winter and grew back with thick stands of coyote willow and cottonwood. The site was completely dry throughout the survey season, and the coyote willow was dead or dying.

We detected no willow flycatchers. We surveyed the site five times throughout the flycatcher breeding season, totaling 8.6 observer-hours. Cowbirds were detected on all surveys. Cattle trails and scat were observed on all surveys, and domestic pigs were seen in the site on one occasion.

Mesquite West

Area: 11.5 ha Elevation: 470 m

This mixed-native site lies within the floodplain of the Virgin River in Mesquite, Nevada. Golf courses and housing developments border the site to the north, and the Virgin River borders the site to the south. This large site is primarily a mosaic of cattail and bulrush marshes separated by narrow (40–50 m) strips of dense coyote willow with interspersed tamarisk. The coyote willows are generally 5–6 m in height, and canopy closure varies from 50 to >90%. Hydrology at the site is influenced by irrigation runoff from adjacent golf courses and agriculture. In previous years, the majority of the site was regularly or continuously inundated. At the beginning of the 2009 breeding season, the site was completely dry, and the pond at the western end of the site, which had previously been too deep to wade, had completely dry soil with deep cracks. Water had previously entered the northeastern corner of the site from a deep trench, but in 2009, what little water was flowing had been diverted down the eastern edge of the site in a trench that had been dug the previous year. During the first site visit in early May, we noted premature leaf abscission in the coyote willows. In the last week of June, we noted surface water within the site for the first time during the season, and it was confined to the eastern portion of the site. This portion of the site received surface water for one day at approximately weekly intervals for the remainder of the breeding season, and the willows appeared to respond with new growth. The rest of the site remained dry, though the cracks in the soil at the western end of the site became shallower, suggesting subsurface water.

We detected 16 breeding willow flycatchers, 1 pair for which no nest was located, and 2 resident, unpaired males. In addition to resident adults, we detected one individual for which residency and

breeding status could not be determined. Areas of Mesquite West not known to be occupied by flycatchers were surveyed once at the beginning of the flycatcher breeding season, totaling 2.0 observer-hours. After the initial survey, all areas of the site were covered by territory monitoring, and surveys were discontinued. Cowbirds were detected on the survey and were detected regularly during territory monitoring. Fresh cattle scat was also observed within the site.

Bunker Marsh North

Area: 13.6 ha Elevation: 456 m

This mixed-exotic site lies within the floodplain of the Virgin River near Bunkerville, Nevada, approximately 4 km downstream of Mesquite West. The site is between agricultural fields to the southeast and the Virgin River to the northwest. We explored and surveyed the riparian vegetation along an approximately 1-km reach of the river. The southern end of the site consists of tamarisk 6 m in height with 50–70% canopy closure. This portion of the site is bordered to the north by a small cattail marsh and a strip of 4–5-m-tall Goodding and coyote willow. The tamarisk area was very dry throughout the season and does not represent suitable flycatcher habitat. The willows surrounding the cattail marsh may provide habitat in future years if the area expands and matures. The remainder of the site is a mosaic of 4–6-m-tall tamarisk, scattered Goodding willow, patches of coyote willow 4–5 m in height, and stream channels and marshy areas. Canopy closure ranges from 25 to 90%. One small patch of coyote willow near the center of the site had surface water beneath the woody vegetation; otherwise, the only portions of the site that contained surface water were the marshes, and soils were dry beneath the woody vegetation. The streams and marshes contained surface water through mid-June but were dry in July.

We detected five breeding willow flycatchers and two flycatchers for which residency and breeding status could not be confirmed. Portions of the site not known to be occupied by flycatchers were surveyed five times, totaling 17.0 observer-hours. Cowbirds were detected on four surveys, and cows were observed in the site on multiple occasions.

Mormon Mesa, Nevada

For approximately 15 km upstream of its outflow to Lake Mead, the Virgin River flows through a 1-km-wide floodplain with a mosaic of habitats, including cattail marshes and tamarisk and willow forest. Much of the area is typically seasonally inundated from snowmelt in the spring and monsoon rains in mid and late summer, and the entire study area experienced severe flooding over the 2004–2005 winter. All the areas surveyed at Mormon Mesa are at least 10 km upstream of Lake Mead. The Virgin River did not go completely dry at Mormon Mesa at any point during the survey season of 2009, unlike in some previous years. Much of the tamarisk throughout Mormon Mesa started yellowing in the middle of June as the result of leaf hopper damage. Cattle were encountered at all sites throughout the survey season.

Mormon Mesa North

Area: 8.2 ha Elevation: 390 m

This mixed-exotic site consists primarily of tamarisk 3–5 m in height with areas of emergent Goodding willow up to 12 m in height and patches of coyote willow. Overall canopy closure is around 50%. The western edge of the site has a 100 x 50 m patch of Goodding willow, 8 m in height, with up to 75% canopy closure and dead cattails in the understory. No standing water or saturated soils were present within the site during the survey season, but surface water was adjacent to the site in May and June in the river channel to the south. The site is perched up to 2 m above the water level. Mormon Mesa North has been completely dry throughout the breeding seasons of 2004 to present, and no flycatchers have been

detected at the site in 2006–2009. Portions of the site, particularly the Goodding willows on the western edge of the site, might provide suitable flycatcher habitat with wetter soil conditions but in recent years have been dry. We recommend visiting this site at the beginning of the survey season to assess hydrologic conditions and discontinuing surveys for the season if the site is completely dry.

We did not detect any flycatchers. We surveyed the site five times, totaling 16.4 observer-hours. Cowbirds were detected on all surveys as was evidence of livestock use.

Hedgerow

Area: 1.1 ha Elevation: 390 m

This mixed-exotic site is east of Mormon Mesa North, on the eastern side of the Virgin River. The site consists of a continuous understory of tamarisk 4–5 m in height with scattered emergent Goodding willow up to 12 m in height. Many of the willows have dead branches. The site is surrounded by tamarisk and arrowweed (*Pluchea sericea*) 2–3 m in height. Canopy closure at the site varies from about 50% on the edges of the site up to 80% in the denser areas. Soils within the site were dry throughout the survey season. No flycatchers have been detected in Hedgerow since we began surveys in 2005, and the site has been completely dry in each year. We recommend visiting this site at the beginning of the survey season to assess hydrologic conditions and discontinuing surveys for the season if the site is completely dry.

We did not detect any flycatchers. We surveyed the site five times, totaling 2.3 observer-hours. Cowbirds were detected on three visits.

Mormon Mesa South

North half: Area: 8.9 ha Elevation: 385 m
South half: Area: 3.4 ha Elevation: 385 m

This mixed-exotic site was split into two contiguous areas to facilitate tracking of survey activity. Habitat evaluation at the beginning of the survey season revealed that the Goodding willow in the western third of the area that had been surveyed in previous years was entirely dead, and we discontinued surveys in this portion of the site. The remainder of the site has scattered Goodding willow up to 20 m in height and a patchy understory of tamarisk 4–7 m in height. Clumps of coyote willow are present on the eastern edge of the site, and dead cattail is present in the understory in this area. Canopy closure is widely variable, ranging from >90% in tamarisk thickets to <50% in openings. There was no surface water within the site, but damp soils were noted on the eastern edge of the site in May and June. The presence of dead cattails and deadfall suggest that this site was formerly considerably wetter, and portions of the site still have the structure to provide potential flycatcher habitat with wetter soil conditions.

No willow flycatchers were detected. We surveyed the northern and southern halves of the site five times each, totaling 12.3 and 7.5 observer-hours, respectively. Cowbirds were detected on all but one survey.

Virgin River #1

North half: Area: 12.0 ha Elevation: 380 m
South half: Area: 34.7 ha Elevation: 380 m

Virgin River #1 was also divided into two areas, Virgin River #1 North and Virgin River #1 South, to facilitate streamlining of field logistics. Habitat assessment in Virgin River #1 North at the beginning of the survey season revealed most of the Goodding willow in the northwestern finger of the area that had

been surveyed in 2008 were dead, and surveys in this area were discontinued. The southeastern corner of the formerly surveyed Virgin River #1 North consists of clumps of tamarisk 4–6 m in height, dry soil, and 60% canopy closure; surveys were discontinued in this area as well. The remainder of Virgin River #1 North is primarily tamarisk 4–6 m in height, with areas of emergent Goodding willow and patches of coyote willow in the central and southwestern portions of the site. Canopy closure throughout the site is 50–70%. Surface water and mud were present in May in channels running north to south through the center of the site, and the southwestern corner of the site also contained surface water in May and June.

We detected three breeding flycatchers and one individual for which residency and breeding status could not be confirmed in the southwestern corner of Virgin River #1 North. Areas of this site not known to be occupied by flycatchers were surveyed five times, totaling 23.5 observer-hours. Cowbirds were detected on all but one survey.

We expanded Virgin River #1 South approximately 600 m to the south and east to explore areas where stream channels were noted on the aerial photograph and during aerial reconnaissance. This new area consists of monotypic tamarisk up to 5 m in height with 70–90% canopy closure. Some of the stream channels contained surface water in May and June and damp soil in July. The channels are incised 1–2 m, and soils beneath the tamarisk were entirely dry throughout the survey season. We do not recommend continuing surveys in this area in future years because of the dry soil conditions. The northwestern portion of the site has coyote and Goodding willows interspersed with tamarisk 4–5 m in height. Goodding and coyote willows average 8 and 5 m in height, respectively. This portion of the site contained surface water throughout the survey season and has open, marshy areas. Canopy closure varies from >90% in areas of dense willow and tamarisk to 25% in marshy openings. The middle portion of the site consists of sparser tamarisk 4 m in height with dry, open areas, and the southwestern part of the site consists primarily of tamarisk 3–5 m in height and canopy closure from 60 to 80%. The southwestern part of the site also contains one cluster of emergent Goodding willow 10 m in height with dead coyote willow in the understory, and tamarisk in this area is up to 8 m in height. Soils in this area were damp, but no surface water was noted. For future years we recommend surveying only the northern third of the site and the area immediately around the Goodding willow cluster in the southwestern portion of the site because of the short canopy height and dry soil conditions in the remainder of the site.

We detected 20 breeding willow flycatchers and 4 unpaired, resident males in the northwestern portion of Virgin River #1 South. We detected four additional willow flycatchers for which residency and breeding status could not be confirmed. Areas of the site not known to be occupied by willow flycatchers were surveyed five times, totaling 29.5 observer-hours. Cowbirds were observed on all surveys.

Virgin River #2

Area: 36.9 ha Elevation: 380 m

This site is primarily a monotypic stand of tamarisk 6 m in height with 70–90% canopy closure. Widely scattered emergent Goodding willow up to 10 m in height are present in the northern half of the site. A clump of Goodding willow occurs halfway down the eastern edge of the site, and scattered willows extend to the southern end of the site. The tamarisk in the willow area are dry and brittle, and a greater proportion of mid-sized tamarisk stems are dead compared to previous years (see Chapter 5). The site contained no surface water during the breeding season, though portions of the site contained damp soils. The Virgin River, on the eastern edge of the site, had surface water throughout the season. No flycatchers have been detected in the northern half of the site from 2003 to present, and we recommend discontinuing surveys in this area.

We detected one willow flycatcher for which residency could not be confirmed. We surveyed the site five times, totaling 51.5 observer-hours. Cowbirds were observed on all surveys.

Muddy River, Nevada

The Muddy River study area is along the Muddy River in the Overton Wildlife Management Area (WMA) near Overton, NV.

Overton WMA Pond

Area: 0.7 ha Elevation: 378 m

This site consists of a patch of mixed-native vegetation approximately 150 m long and 150 m wide at the north end of Overton WMA just south of Honeybee Reservoir. The dominant vegetation consists of 10-m-tall Goodding willow with a sparse 5-m-tall tamarisk understory. Cattail and sedges (*Carex* sp.) are also present on the edges of the site. Canopy closure is variable, ranging up to 90%. A small stream channel runs through the site, and it held surface water throughout the season.

We detected no willow flycatchers. We surveyed the site five times for a total of 3.4 observer-hours. Cowbirds were detected two visits, and no sign of livestock use was observed.

Overton WMA

Area: 14.9 ha Elevation: 378 m

This site consists of a 150-m-wide strip of riparian vegetation spanning both sides of the Muddy River. The site is bordered to the southwest by open agricultural fields and to the northeast by sparser areas of riparian vegetation. The site flooded heavily during the 2004–2005 winter, but vegetation at the site was relatively unchanged. The northern portion of the site is dominated by very dense tamarisk up to 7 m in height with canopy closure of 70–90%. The southern portion of the site consists primarily of a stand of Goodding willow 10–12 m in height with an understory of tamarisk and cattail and canopy closure up to 90%. Flowing water was present in the channel of the Muddy River throughout the survey season. Extensive beaver activity resulted in the southern portion of the site being flooded with approximately 30 cm of water through mid-July, at which time water was restricted to channels and the area that had previously been flooded was only muddy. Beavers have felled swaths of Goodding willow in the southern portion of the site, resulting in gaps in the canopy. Approximately 0.3 ha of the southern portion of the site was bulldozed in 2005 as part of Overton WMA efforts to repair flood damage to their water control system. Two stretches of the channel of the Muddy River within the site were dredged with heavy equipment over the 2007–2008 winter, resulting in a cleared swath 10–15 m wide on the western bank of the river.

We located 11 breeding willow flycatchers and 2 unpaired, resident males. We also detected four flycatchers for which residency could not be confirmed. Portions of the site not known to be occupied by flycatchers were surveyed five times, totaling 21.9 observer-hours. We observed no signs of livestock but detected cowbirds on all surveys.

Ground Reconnaissance Results

THE NARROWS

The Narrows site is along the Muddy River, immediately upstream of the point where the river enters the Moapa Valley, approximately 1.5 km west of Bowman Reservoir. Aerial photographs show a stretch of dense riparian vegetation along the river in The Narrows. This site consists of an approximately 125-m-wide swath of tamarisk straddling a reach of the Muddy River approximately 900 m in length. The site is bordered to the north and south by upland desert. The site is dominated by very dense tamarisk up to 6 m in height with canopy closure of 70–90%, and areas of saltbush (*Atriplex* sp.) border the tamarisk along the southern uplands. Three small, sparse patches of coyote willow and seep willow (*Baccharis* sp.) are found along the river in the central portion of the site. At points along the river where access was possible, flowing water and saturated soil were present only in the river channel. The widest part of the river channel observed was 2.5 m wide and incised up to 2 m. We recommend visiting this site at the beginning of the survey season to assess hydrologic conditions and discontinuing surveys for the season if water is restricted only to the channel.

We surveyed the site three times for a total of 6.5 observer-hours. Cowbirds were detected on two visits, and no sign of livestock use was observed.

MUDDY RIVER RECON

During aerial reconnaissance in March 2009, we noted a flooded area along the riparian corridor of the Muddy River starting approximately 1 km downstream of the southern end of Overton WMA and continuing downstream for approximately 1 km. Ground reconnaissance in May revealed that the area consists primarily of cattail marsh with scattered tamarisk 3 m in height. A few scattered Goodding willow 8 m in height are also present, and overall canopy closure is <25%. The area was flooded with up to 10 cm of water during the site visit. The sparse woody vegetation and open canopy make this area unsuitable for breeding flycatchers.

We visited the site once for a total of 6.0 observer-hours.

Topock Marsh, Arizona

Topock Marsh lies within Havasu NWR and encompasses over 3,000 ha of open water, cattail and bulrush marsh, and riparian vegetation. A large expanse (over 2,000 ha) of riparian vegetation occupies the Colorado River floodplain between the Colorado River on the western edge of the floodplain and the open water of Topock Marsh on the eastern edge of the floodplain. The vegetation is primarily monotypic tamarisk with isolated patches of tall Goodding willow. Seasonally wet, low-lying areas are interspersed throughout the riparian area. Feral pigs are present throughout the Topock study area, and evidence of pigs was observed in all survey sites.

Pipes #1

Area: 5.2 ha Elevation: 140 m

This exotic site is bordered to the east by the refuge road and consists primarily of monotypic tamarisk 5–7 m in height. Arrowweed occurs in dense patches within 50 m of the refuge road. The tamarisk is densest within 100 m of the refuge road and becomes more open toward the western edge of the site. The northern edge of the site has the tallest canopy, and there is relatively little deadfall in this area compared to the rest of the site. The central and southern portions of the site have many dead stems

and clusters of fallen trees. Canopy closure is 70–90%. The site contained no standing water during the survey season but did contain damp soils along the southern edge of the site throughout the season.

We detected one willow flycatcher, for which residency was not confirmed, on 15 May. Three subsequent territory monitoring visits and four subsequent surveys failed to detect the flycatcher again. We surveyed the site five times, totaling 9.0 observer-hours. Cowbirds were detected on all surveys.

Pipes #3

Area: 5.7 ha Elevation: 140 m

This site is bordered to the east by the refuge road. Arrowweed occurs in dense patches within 50 m of the road. Most of the site is vegetated by tamarisk 4–6 m in height. The southeastern portion of the site has a few emergent Goodding willow up to 15 m in height and open, marshy areas. Canopy closure generally exceeds 70%. In May, the portion of the site with Goodding willow and marshes was inundated with up to 10 cm of water, and the central portion of the site had water up to 30 cm in depth beneath the tamarisk. The site progressively dried out through the season but still contained damp soils and standing water in pig wallows in July.

We detected one territorial male flycatcher in Pipes #3. We also detected a second flycatcher at the site on 9 and 13 June. The second flycatcher was interacting with the territorial male and was possibly a female. The second flycatcher was not detected on any of nine territory monitoring visits after 13 June, however. Portions of Pipes #3 not known to be occupied by flycatchers were surveyed five times, totaling 5.3 observer-hours. Cowbirds were detected on three surveys.

The Wallows

Area: 0.4 ha Elevation: 140 m

The Wallows is primarily vegetated by tamarisk 5–6 m in height with emergent Goodding willow on the western side of the site. The northwestern edge of the site borders an open cattail marsh. Overall canopy closure ranges from 50% in the marshy area to 90% in the tamarisk. Half the site was inundated in May, but by mid-June water was present only in intermittent puddles in the marsh, and by mid-July the only remaining surface water was in pig wallows.

We detected two breeding flycatchers and detected another individual on a single occasion on 15 May. Portions of the site not known to be occupied were surveyed 5 times, totaling 5.0 hours. Cowbirds were detected on four surveys.

PC6-1

Area: 4.8 ha Elevation: 140 m

PC6-1 is a mixed-exotic site consisting primarily of tamarisk 6–7 m in height, with a few patches of arrowweed and cattails present in the understory. A scattered overstory of Goodding willow approximately 10–15 m in height is present in the southwestern corner of the site. Arrowweed 1–2 m in height is present under the willow. A portion of the site within approximately 50 m of the refuge road contains thick stands of arrowweed. Canopy closure in the interior of the site is approximately 90%, while canopy closure on the periphery of the site near the refuge road is approximately 50%. Approximately 60% of PC6-1 contained standing water and saturated soils in May. By mid-June only small puddles remained, and <1% of the site had saturated soil in July.

We detected one willow flycatcher between 2 and 6 June. The site was surveyed five times, totaling 11.0 observer-hours. Cowbirds were detected on three surveys.

Pig Hole

Area: 2.4 ha Elevation: 140 m

Pig Hole consists of monotypic tamarisk 6–7 m in height, with canopy closure ranging from 70 to 90%. The northern edge of the site has smaller-diameter tamarisk, with many wispy branches, than the remainder of the site. Approximately 5% of the site consists of dense patches of arrowweed. Approximately 15% of the site had standing water in May, and another 15% of the site had saturated soils. The standing water had disappeared and only 10% of the site contained saturated soils by mid-June, and by mid-July there was no saturated soil in Pig Hole.

No willow flycatchers were detected. The site was surveyed five times, totaling 5.3 observer-hours. Cowbirds were detected on two surveys.

In Between

Area: 7.7 ha Elevation: 140 m

In Between consists of monotypic tamarisk 6–8 m in height. The lowest 3 m of the stand generally lacks foliage, resulting in a relatively open understory. Canopy closure is 70–90%, and the western edge of the site borders a marsh. Approximately 25% of the site was inundated in May, but no standing water remained by mid-July.

We detected no flycatchers in In Between. We surveyed the site five times, totaling 9.8 observer-hours. Cowbirds were observed on all surveys.

800M

Area: 6.1 ha Elevation: 140 m

800M adjoins the western edge of In Between, and the eastern half of the site consists of a cattail and bulrush marsh with clumps of tamarisk 5–7 m in height and scattered, emergent Goodding willow. The remainder of the site is vegetated by tamarisk 4–7 m in height. Canopy closure in the tamarisk is generally >90%, while canopy closure in the marsh is around 50%. The far southern end of the site, within 50 m of the refuge road, consists of very dry tamarisk 3-5 m in height and is not suitable flycatcher habitat. Approximately 40% of the site was inundated in May, but surface water was restricted to a few puddles within the marsh by mid-June.

We detected one resident male flycatcher. Portions of the site not known to be occupied were surveyed five times, totaling 6.5 observer-hours. Cowbirds were observed on all surveys.

Pierced Egg

Area: 6.7 ha Elevation: 140 m

This mixed-exotic site borders the western edge of 800M and consists of dense tamarisk 7 m in height, with a scattered overstory of Goodding willow 15 m in height. Areas with willows tend to have a more open understory and contain patches of cattail and bulrush. Overall canopy closure is approximately

80%. Approximately 40% of the site was inundated in May, but by mid-June, the only remaining water was in deep pig wallows.

We located two resident male flycatchers and three additional flycatchers for which residency could not be confirmed. Two of the additional flycatchers were detected on 16 and 19 June, one in each of the occupied territories, and were suspected to be females. They were not detected on any of eight territory monitoring visits after 19 June. The third flycatcher for which occupancy could not be determined was detected along the refuge road on 8 June. We surveyed portions of the site not known to be occupied by flycatchers five times for a total of 8.5 observer-hours. Cowbirds were observed on all surveys.

Swine Paradise

Area: 1.0 ha Elevation: 140 m

This mixed-exotic site borders the open water of Topock Marsh. Vegetation at the site consists of tamarisk 6–8 m in height and scattered, emergent Goodding willow up to 15 m in height, with patches of coyote willow. Overall canopy closure is approximately 80%. The interior of the site was dry throughout the survey season, but standing water and saturated soils persisted throughout the season in the marsh on the eastern edge of the site.

No willow flycatchers were detected. We surveyed the site five times, totaling 4.0 observer-hours. We detected cowbirds on four visits.

Barbed Wire

Area: 2.4 ha Elevation: 140 m

One large, emergent Goodding willow occurs at the site; otherwise, the site is vegetated by tamarisk 6–10 m in height and of varying density. The northeastern portion of the site contains taller stems, less dead wood in the understory, and fewer large canopy openings than the southwestern portion of the site. Canopy closure is approximately 90%. Standing water was present in pig wallows in May and June.

We detected no willow flycatchers. We surveyed the site five times, totaling 7.3 observer-hours. Cowbirds were detected on three visits.

Platform

Area: 1.3 ha Elevation: 140 m

This site forms a narrow strip of vegetation between the main refuge road and the open marsh. Vegetation at the site consists of tamarisk 7 m in height with a few isolated, emergent Goodding willow. Overall canopy closure is approximately 90%. Bulrush and cattail line the eastern edge of the site adjacent to the marsh. The interior of the site was dry in June and July.

No willow flycatchers were detected. We surveyed the site five times, totaling 3.5 observer-hours. Cowbirds were detected on three visits.

250M

Area: 1.9 ha Elevation: 140 m

This site lies between the main refuge road and the open marsh. Vegetation composition and structure varies with distance from the marsh. Closest to the refuge road the site is dominated by mesquite trees (*Prosopis* sp.) with an understory of arrowweed. The center of the site is dominated by tamarisk approximately 7 m in height. Closest to the marsh, the site contains patches of coyote willow and one emergent Goodding willow approximately 12 m in height. Canopy closure within the site ranges from 70 to 90%. The patch of coyote willow on the northern border of the site was inundated in May and June but dry in July. The remainder of the site was dry throughout the survey season.

We detected three willow flycatchers; one on 21 May, one on 3–7 June, and one on 25 June. Residency could not be confirmed for any of these individuals. The site was surveyed five times, totaling 5.3 observer-hours. Cowbirds were detected on all surveys.

Hell Bird and Glory Hole

Hell Bird: Area: 3.3 ha Elevation: 140 m
Glory Hole: Area: 5.0 ha Elevation: 140 m

These contiguous mixed-exotic sites are located on an island separated from the main riparian area by a narrow, deep channel. Vegetation composition and structure are highly variable, with the survey areas vegetated primarily by a mosaic of tamarisk 6–8 m in height and Goodding willow 15 m in height. Canopy closure ranges from 50 to 90%. The survey areas are bordered on the west by a sand dune and on other sides by dense bulrush. Large swampy areas vegetated by cattail and bulrush are interspersed throughout the survey areas. The proportion of Hell Bird covered by surface water declined from 70% in May to 10% in mid-June and 0% in mid-July. Water levels in Glory Hole declined similarly throughout the season, with 30% of the site being inundated with up to 70 cm of water in early June and only damp soils remaining by mid-July.

We detected two unpaired, resident male flycatchers in Hell Bird and four unpaired, resident males in Glory Hole. In Glory Hole, we detected three additional flycatchers for which residency was not confirmed. Hell Bird was surveyed five times, totaling 10.0 observer-hours. Portions of Glory Hole not known to be occupied by flycatchers were surveyed five times, totaling 1.9 observer-hours. Cowbirds were detected on all surveys in Hell Bird and two surveys in Glory Hole.

Beal Lake

Area: 13.9 ha Elevation: 140 m

This mixed-native restoration site consists of a mosaic of cottonwood, Goodding willow, coyote willow, and arrowweed, with some tamarisk and mesquite scattered throughout the site. Canopy height is highly variable and averages approximately 5 m; canopy closure is sparse, averaging 35%. The amount of standing water and saturated soil is highly variable because it is flood irrigated. Sandy soil at the site allows the water to drain rapidly after irrigation, and the site was dry on all survey visits.

We detected one willow flycatcher on 15–23 May and another on 3 June. A third flycatcher was caught in a mist net at Reclamation's MAPS station on 15 May; this flycatcher was later confirmed to be the breeding male in The Wallows. We surveyed this site five times, totaling 9.3 observer-hours. Cowbirds were detected on four surveys.

Lost Slough

Area: 1.5 ha Elevation: 140 m

Lost Slough is located approximately 4 km south of Glory Hole and Hell Bird. This mixed-exotic site runs northeast to southwest for approximately 250 m, and measures 100 m wide at the broadest point. There is a marshy area in the center of the site; a small area of bulrush is present in the marsh, along with stands of coyote willow 6 m in height. Vegetation around the marsh is composed mainly of 6- to 8-m-tall tamarisk with a few emergent Goodding willow and scattered screwbean mesquite (*Prosopis pubescens*). Arrowweed up to 2 m in height makes up the understory vegetation. Canopy closure at the site is variable, with open areas toward the edges of the site and over 70% closure in areas with thick vegetation. Hydrologic conditions at the site were not assessed in May. In mid-June, the marshy area was inundated, and by mid-July small pools remained in the marsh.

We did not detect any willow flycatchers. We surveyed Lost Slough five times, totaling 5.0 observer-hours. Cowbirds were detected during one survey.

Lost Pond

Area: 1.2 ha Elevation: 140 m

This mixed-exotic site is located approximately 700 m southeast of Lost Slough. The site is approximately 200 m long and 125 m wide, with a small pond at the southern edge of the site and a marshy area at the northern end of the site. The edges of the pond are vegetated with a 30-m-wide border of cattail, bulrush, and sedges. Vegetation within the site consists primarily of tamarisk 4 to 7 m in height with canopy closure approximately 90%. The area surrounding the site consists of arrowweed, 3-m-tall tamarisk, and screwbean mesquite. In May, 75% of the site was inundated, but by mid-June water remained only in the pond and marshy areas adjacent to the site.

No willow flycatchers were detected. We surveyed the site five times, totaling 6.3 observer-hours. Cowbirds were detected during one survey.

Lost Lake

Area: 3.3 ha Elevation: 140 m

This site lies approximately 850 m southeast of Lost Pond. It is a narrow (<100-m-wide) strip of riparian vegetation separated from the Colorado River to the southwest by a low ridge of barren sand dunes and bordered to the northeast by marshy areas. The northern edge of the site consists of an overstory of planted cottonwoods 10–15 m in height, with an understory of tamarisk 5 m in height, on the edge of a cattail marsh. South of the cottonwoods, the site is primarily tamarisk, 5–8 m in height, with small openings vegetated by arrowweed. In previous years, the southeastern end of the site was dominated by dense stands of coyote willow. These willows are now all dead, dramatically reducing the suitability of the site for breeding flycatchers. Overall canopy closure is approximately 80%. The only surface water or saturated soil at Lost Lake was immediately adjacent to the marsh on the northern edge of the site; the interior of the site was dry throughout the survey season.

We detected one willow flycatcher on 29 May. The flycatcher responded to broadcasts but did not vocalize spontaneously. The flycatcher was not detected on three subsequent territory monitoring visits or any of the four subsequent surveys. We surveyed the site five times, totaling 4.5 observer-hours. Cowbirds were detected on four visits.

Ground Reconnaissance Results

NW BEAL LAKE

We explored this area, approximately 600 m northwest of the Beal Lake site, in 2006 after noting a large area of inundated vegetation during aerial reconnaissance. In 2006, vegetation in the area consisted primarily of tamarisk 2–3 m in height with some areas reaching 4 m in height. We returned to this area in 2009 to assess whether vegetation had matured. In 2009, the area was vegetated by tamarisk 3–5 m in height, scattered screwbean mesquite 5–7 m in height, and an understory of arrowweed. Canopy closure was continuous only in low-lying swales; elsewhere, the canopy was broken by open, dry areas in the northwestern portion of the reconnaissance site and by marshes to the southeast. The tamarisk had not grown to a size typical of flycatcher breeding habitat along the LCR. We visited the site once in 2009 for a total of 2.0 observer-hours.

NE LOST LAKE

We explored and surveyed the northern and eastern borders of Lost Lake. Woody vegetation consists entirely of a strip of tamarisk 4 m in height with >90% canopy closure. This strip of tamarisk is 600 m long and generally <50 m wide and is bordered to the west by the cattail marsh on the edge of Lost Lake and to the east by dry uplands vegetated by arrowweed and scattered mesquite. Water from Lost Lake extended into the tamarisk during the site visit in May, but by mid-June surface water was restricted to the cattails and did not extend under the woody vegetation. This site does not have the canopy height typical of occupied flycatcher habitat along the LCR. We surveyed the site four times, for a total of 9.0 observer-hours. No flycatchers were detected. Cowbirds were detected on all visits.

LOST LAKE SOUTH

We explored the area between the southern end of NE Lost Lake and the western tip of the Lost Lake polygon. We had noted this area as being inundated during aerial reconnaissance in March 2009. Vegetation consists of a mosaic of cattail marshes in low-lying areas and a mix of screwbean mesquite, arrowweed, and bulrush in higher areas. Overall canopy closure is <25%, and the vegetation does not resemble that found in occupied flycatcher habitat.

LOST LAKE SLOUGH #1

During aerial reconnaissance in March 2009, we noted several patches of vegetation between the South Dike and New South Dike roads. Lost Lake Slough #1 consists of a 25- x 50-m patch of tamarisk, 4 m in height, 100 m south of the bridge on South Dike Road. The site is surrounded by marsh, but hydrologic conditions within the site were not assessed. Vegetation at the site is too short to resemble typical occupied flycatcher habitat along the LCR. We surveyed the site twice, for a total of 0.5 observer-hour. No flycatchers were detected.

LOST LAKE SLOUGH #2

This native site is approximately 200 m south-southeast of Lost Lake Slough #1. It consists of a 100- x 50-m patch of coyote willow 4 m in height. Canopy closure within the site is around 80%, and the site is surrounded by open marsh. The site was completely inundated in May and had saturated soil in mid-June. Vegetation at the site is currently shorter than that typically found in occupied flycatcher habitat along the LCR, but the site should be monitored in future years to determine if the willows continue to grow or expand to a greater area. We surveyed the site twice, for a total of 1.5 observer-hours. We did not detect any flycatchers and did not detect any other terrestrial birds.

LOST LAKE SLOUGH #3

This mixed-native site is between Lost Lake Slough #2 and New South Dike Road. The site is bordered to the north by marsh and to the south by dry uplands adjacent to the road. Vegetation within the site is a mix of coyote willow and tamarisk, both around 4 m in height. Canopy closure is around 65% at the eastern edge of the site and decreases toward the west. Approximately half the site was inundated in May, but only the edge adjacent to the marsh had standing water in mid-June. This site does not currently have the canopy height or canopy closure typical of occupied flycatcher habitat along the LCR but should be monitored for changes in vegetation in future years. We surveyed the site twice, for a total of 1.0 observer-hour.

LOST LAKE SLOUGH #4

This mixed-native site is approximately 100 m west of Lost Lake Slough #3 and lies between marsh to the north and dry uplands to the south. Vegetation at the site grades from a mix of coyote willow and bulrush on the northern border to coyote willow in the middle of the site and tamarisk on the upland edge of the site. Canopy height in the willows is 3 m while the tamarisk reaches 4 m. Canopy closure is around 90%. This site does not currently have the canopy height typical of occupied flycatcher habitat along the LCR but should be monitored for changes in vegetation in future years. We surveyed the site twice, for a total of 2.0 observer-hours.

MARINA

This site is immediately north of the Topock Gorge Marina and extends for approximately 500 m north, between marsh to the east and dry uplands to the west. The site is less than 50 m wide and grades from a mix of coyote willow and arrowweed along the eastern border to a mix of tamarisk, arrowweed, and screwbean mesquite on the western edge. Canopy height ranges from 3 m in the willows to 4–6 m in the tamarisk, and canopy closure is highly variable, averaging around 60%. Surface water was present only along the eastern edge of the site and did not extend more than a few meters under the woody vegetation. This site does not have the canopy closure typical of occupied flycatcher habitat along the LCR. We surveyed the site three times, totaling 7.3 observer-hours.

Topock Gorge, Arizona and California

Between Topock Marsh and Lake Havasu, the Colorado River winds through Topock Gorge. Throughout the Gorge, the river is confined between steep cliffs and high bluffs, and little vegetation grows along the river. We surveyed backwater areas that support marsh and riparian vegetation.

Pulpit Rock

Area: 2.1 ha Elevation: 140 m

This mixed-exotic site lies where an unnamed wash enters the Colorado River from the Mohave Mountains. The northwestern edge of the site is vegetated by cattails and borders a backwater, and the upland edge is vegetated by arrowweed, honey mesquite (*Prosopis glandulosa*), and ironwood (*Olneya tesota*). Vegetation within the site consists primarily of tamarisk up to 5 m in height, with small patches of coyote willow near the marsh edge. Canopy closure is around 80% near the marsh but only 30% at the upland edges of the site. Hydrologic conditions at the marsh interface were not assessed, but the majority of site appeared to by dry.

No willow flycatchers were detected. We surveyed the site five times, for a total of 2.5 observer-hours. Cowbirds were detected on one survey, and we observed burro tracks and trails around the site. One migrant willow flycatcher has been detected at this site since we began surveying it in 2003. The small size of the site, its isolation from other riparian habitat, and its predominantly dry soils make this site unlikely to support resident flycatchers. We recommend discontinuing surveys at this site.

Picture Rock

Area: 4.6 ha Elevation: 138 m

This mixed-exotic site consists of two patches of riparian vegetation where an unnamed wash enters the Colorado River from the west. Vegetation within the site consists primarily of tamarisk 5–6 m in height, scattered Goodding willow 12 m in height, and one small patch of coyote willow. Bulrush and cattail are present on the edge of the site along the river, and the upland edges of the site contain arrowweed, mesquite, and paloverde (*Parkinsonia* sp.). Canopy closure within the tamarisk is 70–90%. During surveys, surface water was confined to the edge of the site adjacent to the marsh and did not extend under the woody vegetation.

No willow flycatchers were detected. We surveyed the site five times, for a total of 7.3 observer-hours. Cowbirds were detected on two surveys, and burro tracks and trails were observed around the site.

Blankenship Bend North

Area: 26.7 ha Elevation: 138 m

Blankenship Bend contains riparian and marsh vegetation along the eastern bank of the Colorado River adjacent to the Blankenship Valley. The eastern edge of Blankenship Bend North consists of a 100-m-wide strip of vegetation that grades from mesquite 7 m in height at the upland edge to tamarisk and then to a narrow strip of coyote willow 5 m in height. The coyote willow borders a bulrush marsh, and the western edge of the marsh is also vegetated by a narrow (5–10-m-wide) strip of coyote willow as well as several emergent Goodding willow 12 m in height. The remainder of Blankenship Bend North extends for another 400 m to the west until it reaches the open water of the Colorado River. This portion of the site consists of a mosaic of marshes, tamarisk, coyote willow, arrowweed, and mesquite. Vegetation height generally does not exceed 5 m, and canopy closure within the woody vegetation varies between 60 and 80%.

We detected no flycatchers at Blankenship Bend North. We surveyed the site five times, totaling 18.3 observer-hours. We detected cowbirds on all surveys, and evidence of feral pigs and burros was observed.

Blankenship Bend South

Area: 25.9 ha Elevation: 138 m

The eastern edge of Blankenship Bend South consists of a 100-m-wide strip of tamarisk up to 6 m in height with clumps of emergent Goodding willow up to 12 m in height. This strip of vegetation is bordered to the east by dry, upland vegetation and to the west by bulrush marsh and open water. Between this strip of vegetation and the river, approximately 600 m to the west, the site consists primarily of bulrush marsh with widely scattered clumps of tamarisk up to 5 m in height. Canopy closure is approximately 80% in the eastern portion of the site and less than 50% in the remainder of the site. Because woody vegetation in the western portion of the site is widely scattered, we recommend

discontinuing surveys in this portion of the site in future years. The site contained standing water throughout the survey season, with up to 80% of the site inundated.

We detected no flycatchers at Blankenship Bend South. We surveyed the site five times, totaling 14.3 observer-hours. We detected cowbirds on all surveys but did not observe signs of livestock.

Bill Williams River National Wildlife Refuge, Arizona

The Bill Williams River NWR contains the last expanse of native cottonwood-willow forest in the LCR region. The refuge encompasses over 2,500 ha along the Bill Williams River upstream from its mouth at Lake Havasu and contains a mixture of native forest, stands of monotypic tamarisk, beaver ponds, and cattail marsh. Survey sites within Bill Williams are listed below from west to east, moving progressively farther upstream. We did not observe evidence of livestock use at any of the Bill Williams sites.

In addition to the regularly scheduled surveys, we revisited one site located in previous years that was determined to be potentially suitable flycatcher habitat. Results of this habitat evaluation are presented following the survey results.

Burn Edge

Area: 3.7 ha Elevation: 140 m

Burn Edge is near the northern edge of the Bill Williams riparian corridor, on the eastern edge of an area that burned in 2006. A cattail marsh with Goodding willow and cottonwood 15 m in height runs east-west through the center of the site. This portion of the site also has clumps of tamarisk up to 6 m in height. Canopy closure in the marshy area varies from around 60% at the eastern end to 25% at the western end. The area on either side of the marsh consists of tamarisk 6 m in height with up to 90% canopy closure. The entire marshy area was inundated in May to a depth up to 40 cm. Intermittent pools were present in mid-June, and by late July only two puddles remained.

No willow flycatchers were detected at Burn Edge. We surveyed the site five times, totaling 5.8 observer-hours. Cowbirds were detected on four visits.

Bill Williams Site #4 and Site #3

Site #4: Area: 9.9 ha Elevation: 140 m
Site #3: Area: 9.5 ha Elevation: 140 m

These two sites are contiguous and together are known as Mosquito Flats. Vegetation is mixed-native, with an overstory of Goodding willow 15–20 m in height and patches of monotypic tamarisk up to 8 m in height. Patches of coyote willow are also present. Canopy closure is variable and overall is approximately 50%. Stands of cattails and marshy areas occupy approximately 10% of Site #3. The understory in some areas is very open, and the ground in these areas is covered with herbaceous vegetation. Many large willows and cottonwoods have fallen over the past several years, leaving large gaps in the canopy and creating patches of thick, dead, fallen woody vegetation. Mosquito Flats had a network of small, flowing streams in May, but these had dried to damp soil by July. The marshes in Site #3 were dry by July, and the only surface water remaining in Mosquito Flats was in the northwestern corner of Site #4 in a deep backwater channel.

We detected two resident, male flycatchers in Site #4 and detected two additional flycatchers for which residency was not confirmed. One of these was observed on 16–18 June in one of the occupied territories

and was suspected to be a female, though it was not observed on any of five subsequent territory monitoring visits. Eight breeding flycatchers were detected in Site #3. Portions of the sites not known to be occupied by flycatchers were visited five times, totaling 14.3 observer-hours at Site #4 and 7.3 observer-hours at Site #3. Cowbirds were detected on all surveys of Mosquito Flats.

Last Gasp

Area: 2.1 ha Elevation: 140 m

Last Gasp is a narrow, mixed-native site along a channel on the northern edge of the Bill Williams riparian area, approximately 250 m east of Burn Edge. Vegetation within the site consists of a broken overstory of cottonwood and Goodding willow 15–20 m in height and a tamarisk understory 5–7 m in height. The bottom of the channel is 1–2 m below the surrounding ground surface. Canopy closure varies from 50% in the channel to 80–90% in the surrounding tamarisk. The channel contained intermittent pools in May. One pool remained in mid-June, and by mid-July no surface water was present.

No willow flycatchers were detected at Last Gasp. We surveyed the site five times, totaling 7.0 observer-hours. Cowbirds were detected on all visits.

Bill Williams Site #5

Area: 6.8 ha Elevation: 143 m

Site #5 is located on the eastern edge of the Bill Williams River floodplain and is bordered to the northeast by steep cliffs and to the west by a dry river channel. The survey site was expanded in 2008 approximately 350 m upstream, and in 2009 we ceased surveying the most downstream 250 m of the site. The discontinued area consists of deep pools surrounded by completely dry, patchy tamarisk 4 m in height and does not resemble occupied flycatcher habitat. Vegetation in the site is mixed-native, with Goodding willow and cottonwood 15–20 m in height in the overstory. The understory consists of tamarisk 7 m in height as well as some young Goodding willow and cottonwood. Ground cover in portions of the site consists of thick, dead, fallen woody vegetation. Canopy closure in the site is variable, ranging from 25% in open areas to 70–90% in the denser vegetation. Soils in the majority of the site were dry, although a couple of small ponds and marshy areas along the cliff on the northeastern edge of the site contained water through July.

We detected one unpaired, male flycatcher in Site #5. Portions of the site not known to be occupied were surveyed five times, totaling 10.0 observer-hours. Cowbirds were detected on four surveys.

Upstream from Site #8

Area: 1.5 ha Elevation: 170 m

Vegetation in the majority of the site consists of an overstory of cottonwood and Goodding willow up to 15 m in height and an understory of tamarisk. The western third and southern edge of the site are vegetated by Goodding willow and cottonwood up to 10 m in height. The northern edge of the site borders a cattail marsh. Canopy cover is variable and ranges from 50 to 80%. The central portion of the site was inundated throughout the breeding season.

We detected two breeding flycatchers. Portions of the site not known to be occupied were surveyed five times, totaling 4.0 observer-hours. Cowbirds were detected on three visits.

Planet Ranch Road

Area: 2.1 ha Elevation: 170 m

This mixed-native site follows the Bill Williams River at the southern edge of the riparian area. The northern bank of the river is steep and is vegetated by tamarisk and arrowweed perched well above the level of the river. The southern bank is more gradual, and beaver activity along the river has resulted in flooding on this bank. Vegetation on this side of the river consists of an overstory of Goodding willow and cottonwood up to 15 m in height and an understory of tamarisk 5 m in height. Overall canopy closure in this portion of the site is 70–90%. The river and the willow stand on the southern bank had surface water throughout the survey season.

No flycatchers were detected. We surveyed the site five times, totaling 5.8 observer-hours. We detected cowbirds on all surveys.

Ground Reconnaissance Results

PLANET RANCH

This site starts 200 m east of Upstream from Site #8, and extends 400 m east of the starting point. We visited this site in 2007 and 2008 and noted that the central portion of it had vegetation structure resembling that of occupied flycatcher habitat but that surface water was generally lacking. We revisited the site in late May and early July 2009 to determine whether hydrologic conditions had changed. Surface water was present in small pools along approximately 25 m of a stream channel near the north edge of the site, which borders a cattail marsh. Overall, <1% of the site contained surface water. We surveyed the site twice, totaling 2.8 observer-hours.

Ahakhav Tribal Preserve, Arizona

The Ahakhav Tribal Preserve encompasses backwater areas along the Colorado River near Parker, Arizona, and includes restoration sites. We surveyed a portion of Deer Island.

Deer Island

Area: 15.2 ha Elevation: 104 m

This site consists of a narrow strip of mixed-native vegetation on the edge of a long backwater slough. The only dense, woody vegetation occurs in a strip approximately 5 m wide on the edge of the slough and consists of tamarisk and screwbean mesquite up to 6 m in height and an understory of arrowweed. More than 5 m from the water, vegetation is primarily arrowweed with widely scattered tamarisk and mesquite. Canopy closure is <50%. The southern side of the slough has a steep, high bank, and woody vegetation is perched several meters above the water level. The north bank is not as high, with woody vegetation approximately 1 m above the water level. Although extensive areas of inundated soils existed in the slough and the adjacent cattails, water did not extend into the woody vegetation at any time during the survey season. The majority of the site burned between 2 and 8 July, and surveys were discontinued.

We detected no willow flycatchers. We surveyed the site four times, totaling 4.0 observer-hours. Cowbirds were detected on all visits. No evidence of livestock use was observed.

Palo Verde Ecological Reserve, California

PVER Phase 2

Area: 28.7 ha Elevation: 85 m

This habitat creation site is vegetated with a mosaic of cottonwood, Goodding willow, and coyote willow, which reach heights of 8, 7, and 4 m, respectively. Height and density of the vegetation varies within as well as between cells of the site. Canopy closure is highly variable, ranging from <25 to 80%. The entire site has a ground covering of alfalfa (*Medicado sativa*). The site is flood irrigated but did not contain surface water during any of our site description visits. The irrigation canal adjacent to the site contained water throughout the season.

We detected one willow flycatcher on 27 May and one on 3 June. We surveyed the site five times, totaling 15.0 observer-hours. Large numbers of cowbirds were detected on all visits, and no evidence of livestock use was recorded.

Big Hole Slough, California

Big Hole Slough

Area: 29.0 ha Elevation: 82 m

This mixed-native site consists of cattail marshes edged with narrow bands of coyote willow 5 m in height. In upland areas away from the marshes, the site contains tamarisk and honey and screwbean mesquite up to 8 m in height with an understory of arrowweed. A few tall Goodding willow and cottonwood are present at the site. Overall canopy closure is approximately 50%. The site is surrounded by agricultural fields. The marsh contained standing water throughout the survey season.

We detected one willow flycatcher on 17 June. The site was surveyed five times, totaling 17.0 observer-hours. Cowbirds were detected on all visits, often in large flocks. No livestock use was observed.

Cibola National Wildlife Refuge, Arizona and California

CVCA Phase 1

Area: 26.2 ha Elevation: 73 m

This habitat creation area consists of a mosaic of rectangular cells of cottonwood, Goodding willow, and coyote willow of varying size and density. Each cell generally contains a single species and age class. The tallest cottonwoods and willows are around 9 m in height, and canopy closure in the densest areas is 80–90%. Coyote willow reaches 3–5 m in height. The site is flood irrigated but did not contain standing water during any of our site description visits. The Colorado River is about 100 m from the northern edge of the site, and the remaining three sides are surrounded by agriculture. The irrigation canal adjacent to the site held surface water throughout the season.

We detected one willow flycatcher on 27 May. The site was surveyed five times, totaling 17.0 observer-hours. Large flocks of cowbirds were detected on all visits, and no evidence of livestock use was observed.

CVCA Phase 3

Area: 41.2 ha Elevation: 73 m

This habitat creation area consists of a mosaic of rectangular cells of cottonwood, Goodding willow, and coyote willow of varying size and density. The tallest cottonwoods reach 7–8 m, Goodding willow reach 6 m, and coyote willow reach 3 m. Canopy closure varies from 20 to 80%. The site is flood irrigated but did not contain standing water during any of our site description visits. The site is surrounded by agricultural fields. The irrigation canal adjacent to the site held water throughout the season.

We detected one willow flycatcher on 16 May, one on 27 May, and two on 10 June. The site was surveyed five times, totaling 15.8 observer-hours. Large flocks of cowbirds were detected on all visits, and no evidence of livestock use was observed.

Cibola Nature Trail

Area: 13.7 ha Elevation: 70 m

This habitat creation site consists of a mosaic of cottonwood, Goodding willow, and mesquite. Approximately half the site consists of scattered screwbean and honey mesquite up to 5 m in height with a thick understory of seep willow. The northern half of the site contains an extensive stand of Goodding willow 8 m in height. The northern edge of the willow stand has canopy closure <25% and many of the willow are dead. The southern half of the willow stand has canopy closure around 70%. The southwestern corner of the site has a small stand of cottonwoods, and stringers of cottonwoods up to 18 m in height occur throughout the site. The site is flood irrigated and contained varying amounts of surface water through the season.

We detected one willow flycatcher on 16 May, two on 27 May, and one on 10 June. The site was surveyed five times, totaling 4.6 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

Cibola Island

Area: 4.2 ha Elevation: 70 m

This mixed-native site is approximately 9.5 km southwest of Cibola Nature Trail. The site runs north to south, extending approximately 500 m lengthwise, with a width of 100 m. Dirt roads border the site to the north, east, and west. Open farm fields lie across the eastern road, with irrigation channels alongside the road. An irrigation canal empties into the northern end of the site, creating an open, marshy area down the center of the site. Between this marshy area and the western road, vegetation consists of an overstory of Goodding willow 10–12 m in height with an understory of tamarisk 5–7 m in height. Canopy closure within the willows is 80%. The eastern edge of the marsh is lined with a narrow strip of tamarisk 5–6 m in height with a few emergent Goodding willows on the marsh edge. Between the tamarisk strip and the eastern road, vegetation consists of honey mesquite and bushy arrowweed. The marsh was inundated with up to 50 cm of water in May, but in June and July the marsh contained only small pools.

We detected four willow flycatchers on 26 May and three on 4 June. The site was surveyed five times, totaling 5.1 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

Cibola Site #2 and Cibola Site #1

Cibola Site #2: Area: 16.4 ha Elevation: 65 m
Cibola Site #1: Area 7.7 ha Elevation: 65 m

These adjacent, mixed-exotic sites consist of a 200-m-wide strip of riparian vegetation between the channelized Colorado River to the west and a levee road to the east. Woody vegetation consists of a mix of tamarisk and arrowweed, 3–4 m in height, which is dry and scrubby on the eastern edge of the sites and becomes denser toward cattail marshes on the western edge of the sites. Emergent Goodding willow and cottonwood are scattered along the eastern edge of the marshes. Overall canopy closure is less than 50%. No surface water was present within the sites during the survey season.

We detected one willow flycatcher on 9 June at Cibola Site #1. We surveyed each site five times, totaling 7.1 hours at Cibola Site #2 and 5.3 hours at Cibola Site #1. Numerous cowbirds were detected on all surveys, and burros were observed using the periphery of the sites.

Hart Mine Marsh

Area: 31.6 ha Elevation: 65 m

This mixed-exotic site parallels the channelized Colorado River immediately south of Cibola Site #1. The site consists of a mix of tamarisk and linear stretches of marsh, which make up about 30% of the site. Height of the tamarisk does not exceed approximately 5 m, and reaches this height only within 20 m of the marshes. Away from the marshes, the tamarisk is 3 m in height and partially dead. Canopy closure within the densest tamarisk is 80–90%. An open channel had been dredged down the middle of the northern third of the site. The marshes contained standing water throughout the survey season, but water did not extend under the woody vegetation. The site lacks the height and extent of woody vegetation typical of occupied flycatcher habitat along the LCR, and surveys were discontinued in July.

No willow flycatchers were detected. We surveyed the site four times, for total of 7.8 observer-hours. Cowbirds were detected on all surveys, and burros were observed on the periphery of the site.

Cibola Lake East

Area: 4.5 ha Elevation: 64 m

This site borders the marsh on the eastern edge of Cibola Lake. Vegetation within the site consists primarily of tamarisk. Within 30 m of the marsh edge, tamarisk reaches 6–7 m in height and 90% canopy closure. As distance from the marsh increases, the height and density of the tamarisk decreases, and the tamarisk becomes mixed with arrowweed. Soil within the site was dry throughout the survey season.

We detected one willow flycatcher on 4 June. We surveyed the site five times, totaling 6.3 observer-hours. Cowbirds were detected on all visits, and burro sign was observed on the periphery of the site.

Walker Lake

Area: 11.4 ha Elevation: 64 m

This mixed-exotic site is located along the northeastern edge of Walker Lake. The majority of the site consists of very dense tamarisk approximately 5 m in height with 90% canopy closure. The southeastern end of the site contains scattered emergent Goodding willow up to 20 m in height, as well as a couple of

emergent cottonwoods. This portion of the site also contains a small opening with dead cattails and a small patch of half-dead coyote willow. Walker Lake contained standing water and saturated soil throughout the survey season. Areas of the site adjacent to Walker Lake had saturated soils in May, though these soils were only damp in June and July. Soils in the interior of the site were dry throughout the survey season.

We detected no willow flycatchers. The site was visited five times, totaling 11.4 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

Imperial National Wildlife Refuge, Arizona and California

Paradise

Area: 7.8 ha Elevation: 62 m

The center of this mixed-native site consists of stringers of cottonwood and Goodding willow 15–20 m in height. Tamarisk (5 m in height) and arrowweed (3 m in height) make up the understory. The cottonwoods and willows are separated from the Colorado River by a narrow (50-m-wide) strip of dense tamarisk. A marsh borders the western side of the southern third of the site. This marsh had been vegetated by cattails in previous years but now consists primarily of common reed (*Phragmites australis*). Canopy closure within the site is variable. Standing water was present within the marsh in May.

We detected one willow flycatcher on 20 May. The site was surveyed five times, totaling 6.8 observer-hours. Cowbirds were detected on every visit, and burros were noted near the site.

Hoge Ranch

Area: 20.7 ha Elevation: 61 m

This mixed-exotic site is dominated by tamarisk 4–6 m in height, with a few emergent cottonwood and Goodding willow (15 to 18 m in height) at the southern end of the site near the old ranch. Linear marshes with cattail, bulrush, and common reed occupy less than 20% of the interior of the site, and there are a few patches of coyote willow. Canopy closure is variable and reaches 70–90% in areas of dense, woody vegetation. The marshes in the interior of the site contained small pools of water in July. The site also borders the Colorado River.

We detected three willow flycatchers on 20 May and one on 15 June. The site was surveyed five times, totaling 9.7 observer-hours. Cowbirds were detected on four surveys, and there was evidence of burros using the site.

Rattlesnake

Area: 7.6 ha Elevation: 60 m

This mixed-exotic site is a patchwork of tamarisk 7 m in height with emergent Goodding willow up to 15 m in height and strips of dense coyote willow 6–8 m in height. Canopy closure is 70–90%. Extensive cattail marshes separate this site from the Colorado River. The interior of the site contained no standing water during the survey season.

We detected one willow flycatcher on 19 May. The site was surveyed five times, totaling 6.1 observer-hours. Cowbirds were detected on all surveys, and there was no evidence of livestock use.

Milemarker 65

Area: 10.0 ha Elevation: 58 m

The site is a narrow strip of mixed-exotic vegetation between the Colorado River and a backwater marsh. Vegetation at the site consists primarily of dense tamarisk 6 m in height. Dense common reed, approximately 3 m in height, also occurs throughout the site and together with the tamarisk creates almost complete canopy closure. Because of the impenetrable vegetation at the site, we surveyed it from the river, and hydrologic conditions in the interior of the site during the surveys are unknown.

No willow flycatchers were detected. We surveyed the site five times for a total of 2.9 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Nursery NW

Area: 7.0 ha Elevation: 58 m

This mixed-exotic site lies between the Colorado River and a cattail marsh. The dominant vegetation is tamarisk approximately 5 m in height with an understory of common reed. Mesquite trees are scattered along the western edge of the site. The eastern edge of the site, adjacent to the cattail marsh, has a stand of Goodding willow 9 m in height. Overall canopy closure is around 70%, and the densest portions of the site have canopy closure >90%. Surface water was present in the adjacent marsh in May and June.

We detected one willow flycatcher on 16 June. The site was surveyed five times, totaling 4.4 observer-hours. Cowbirds were detected on all visits, and there was no evidence of livestock use.

Ferguson Lake

Area: 21.1 ha Elevation: 57 m

The Ferguson Lake site is on a strip of land between Ferguson Lake and the Colorado River. Vegetation is mixed-native, with scattered, emergent Goodding willow 10 m in height along the western edge of the site bordering Ferguson Lake. Tamarisk 5–6 m in height is the dominant understory species, and it forms a continuous canopy in portions of the site. The site also contains patches of arrowweed with scattered screwbean mesquite and little canopy cover. The northwestern corner of the site up to 50 m from the lakeshore had damp soils in May and standing water in June and July.

We detected three willow flycatchers on 21 May and two on 16 June. The site was surveyed five times, totaling 16.8 observer-hours. Cowbirds were detected on all visits, and no signs of livestock use were observed.

Great Blue Heron

Area: 7.1 ha Elevation: 58 m

This site, on the eastern shore of Martinez Lake, consists of mixed-exotic vegetation. Near the shore of Martinez Lake, Goodding willow forms an overstory 15 m in height, with an understory of tamarisk, common reed, and giant reed (*Arundo* sp.). Canopy closure in this area is 80%. Portions of the site contain thickets of willow deadfall. Farther from the lake, the site is vegetated by scattered arrowweed and tamarisk 6 m in height, with canopy closure <50%. The site and the adjacent marsh were dry in

May and June. Pools of water within the woody vegetation were noted in July after thunderstorms the previous night.

We detected one willow flycatcher on 28 May and one on 12 June. The site was surveyed five times, totaling 19.4 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Powerline

Area: 2.0 ha Elevation: 58 m

This mixed-native site consists of a strip of Goodding willow and cottonwood along the border of a cattail marsh. Overstory height is approximately 12 m and canopy closure is <50%. Tamarisk and arrowweed are present in the understory, and honey mesquite is mixed with the tamarisk on the upland edge of the site. Small pools of water were present within the marsh in May and July, but the marsh was dry in June.

We detected one willow flycatcher on 28 May. We surveyed the site five times, totaling 6.3 observer-hours. Cowbirds were detected on all visits, and burro tracks and scat were noted within the site.

Martinez Lake

Area: 4.6 ha Elevation: 58 m

This mixed-native site borders the eastern shore of Martinez Lake. The eastern edge of the site, adjacent to the upland, is dominated by arrowweed with scattered Goodding willow, cottonwood, and tamarisk. Goodding willow <10 m in height and cottonwood up to 15 m in height are more prevalent on the western edge of the site, adjacent to cattails and common reed along the lakeshore. Canopy closure is highly variable. No surface water was recording within the site at any time during the survey season, and the marsh edge adjacent to the site was also dry.

No willow flycatchers were detected. We surveyed the site five times, totaling 6.0 observer-hours. Cowbirds were detected on all visits, and burro tracks and scat were observed at the site.

Ground Reconnaissance Results

IMPERIAL BURN

This area is between Nursery NW and the uplands to the northeast. A prescribed burn is being considered for this area, and Reclamation requested that we evaluate it. We visited the area on 30 May. It consists of a mosaic of tamarisk and marshy openings. Scattered mesquite trees emerge 1–3 m above the tamarisk, and the area also contains a few widely scattered Goodding willow, which also emerge a few meters above the tamarisk. Surface water did not appear to extend beyond the borders of the marshes. Canopy height and density were not recorded during the site visit, and it is difficult to determine the suitability of the site for willow flycatchers from the limited data available.

Mittry Lake, California

Mittry West

Area: 4.4 ha Elevation: 48 m

The center of this mixed-native site is dominated by Goodding willow 12 m in height with a dense understory of arrowweed and tamarisk. Canopy closure is approximately 80%. Honey and screwbean mesquite are scattered throughout the site but are more common near the periphery. Surface water was present in the site during May, but the site was dry in June and July and a small patch of cattails within the site was noted in June as being primarily dead.

We detected two willow flycatchers on 11 June. The site was visited five times, totaling 7.9 observer-hours. Cowbirds were detected during all surveys, and no evidence of livestock use was observed.

Ground Reconnaissance Results

LAGUNA DAM NORTH

We investigated this area, northwest of Mittry West between Imperial Road and the All American Canal, after receiving reports of willow flycatcher detections from personnel from an unrelated project. Vegetation in the area consists of a mix of honey mesquite up to 8 m in height and tamarisk 4 m in height. Scattered Goodding willow up to 6 m in height is also present. Canopy closure is 50–70%. Soils within the site were completely dry at the end of May. The site does not have the vegetation density or mesic conditions typical of occupied flycatcher habitat, and we discontinued surveys after three visits. We detected one willow flycatcher on 29 May and one on 11 June. No flycatchers were detected on 26 June.

Yuma, Arizona

Gila River Site #2

Area: 5.1 ha Elevation: 45 m

The center of this mixed-native site consists of an overstory of cottonwood up to 15 m in height and Goodding willow approximately 8 m in height, with an understory of arrowweed. Canopy closure in the center of the site is 70–90%. The remainder of the site is vegetated by tamarisk 4 m in height and arrowweed, with canopy closure <50%. The site is bordered to the north by agricultural fields and to the south by an open, sandy area vegetated by arrowweed. There was no standing water within the vegetation during the survey season, but the northwestern edge of the site borders a marsh, which held water throughout the season.

We detected three willow flycatchers on 30 May and one on 14 June. The site was surveyed five times, totaling 8.2 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Fortuna Site #1

Area: 5.1 ha Elevation: 45 m

This mixed-native site consists of a narrow strip of cottonwood and Goodding willow up to 15 m in height with 50–70% canopy closure. Tamarisk and arrowweed form a patchy understory on the periphery of the site. Within the densest cottonwood/willow areas, there is little understory but many downed branches. The site is bordered to the north by agricultural fields and to the south by a cattail marsh and the Gila River. Surface water was recorded in the lowest portion of the site in May, but the entire site was dry in June and July.

We detected two willow flycatchers on 31 May. We surveyed the site five times, totaling 5.3 observer-hours. Large numbers of cowbirds were detected on all visits, and no evidence of livestock use was observed.

Fortuna North

Area: 3.4 ha Elevation: 46 m

This site is vegetated primarily by mature tamarisk approximately 7 m in height. Goodding willow and mesquite, also 7 m in height, are scattered throughout the site but make up less than 10% of the vegetation. Canopy closure is approximately 80%. The western edge of the site borders the Gila River. No surface water was noted within the site during the survey season.

We detected no willow flycatchers at this site. We surveyed the site five times, totaling 6.3 observer-hours. Large numbers of cowbirds were detected on all visits, and no evidence of livestock use was observed.

DISCUSSION

Six areas occupied in 2009 by breeding flycatchers (Pahranagat NWR, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams River NWR) consistently held resident and breeding flycatchers in previous years (McKernan and Braden 2002, McLeod et al. 2008, McLeod and Koronkiewicz 2009; details of residency and breeding in 2009 are presented in Chapters 3 and 4 of this document). In 2009, breeding flycatchers were recorded along Beaver Dam Wash at Littlefield (Littlefield Poles) for the first time since 2004. We detected breeding flycatchers for the first time at Bunker Marsh North on the Virgin River. SWCA personnel from an unrelated flycatcher survey project detected no flycatchers at Bunker Marsh North in 2004, and we did not detect flycatchers at the site during habitat reconnaissance and opportunistic surveys in 2006. Bunker Marsh North was surveyed in 2009 based on findings of aerial reconnaissance prior to the survey season when we noted areas of inundated vegetation. Along the Bill Williams River, breeding flycatchers were detected at a new breeding site, Upstream from Site #8. We did not detect flycatchers at Upstream from Site #8 during habitat reconnaissance and opportunistic surveys in 2007 and 2008.

Factors in addition to the presence of standing water during the breeding season appear to be influencing the presence and numbers of breeding flycatchers at Topock Marsh. The amount of standing water throughout the entire Topock study area was markedly reduced in 2005 compared to 2003–2004 and 2006–2008. In 2009, water levels at Topock were as high during flycatcher settlement in May and early June as they had been in previous wet years, but sites dried out earlier in the season than in previous years. The number of flycatchers recorded at Topock since 2003 does not appear to be related solely to

the amount of standing water present during the breeding season, with 25, 67, 41, 37, 31, 30, and 28 adults recorded in 2003–2009, respectively. Factors such as reproductive rates, survival, changes in breeding habitat (see Chapter 5), or other abiotic conditions may be influencing the demographics of this local population. Hydrologic conditions within the sites at Topock prior to mid-May of each year are largely unknown and may influence habitat conditions and flycatcher occupancy. Marsh elevation data obtained for 2006 to 2009 suggest no interannual changes in the amount of water present in the vegetation prior to flycatcher arrival in those years. Marsh elevation data for years prior to 2006 are not available.

In an effort to locate all potentially suitable willow flycatcher habitat at Topock Marsh, we conducted habitat reconnaissance and opportunistic surveys at eight sites. Of the eight sites, one was visited in 2006 and seven were noted as containing areas of inundated vegetation during aerial reconnaissance in 2009. Three of the eight sites currently do not have the vegetation structure typical of occupied flycatcher habitat along the LCR but should be monitored for changes in vegetation in future years. Five of the areas we visited are unlikely to support flycatchers in future years, as it is unlikely that habitat conditions will improve.

Although 40 flycatchers were recorded at sites surveyed south of the Bill Williams on or before 15 June, and four detections were recorded post 15 June, monitoring results and behavioral observations (lack of territorial, aggressive behaviors exhibited toward conspecific broadcasts) at these sites suggest these flycatchers were not resident or breeding individuals but migrants. These results are consistent with those recorded in 2003–2008 (McLeod et al. 2008, McLeod and Koronkiewicz 2009).

In 2008, we implemented a biennial survey schedule at selected sites. At this time, we are not recommending the addition of any sites to the biennial schedule for 2010.

Chapter 3

COLOR-BANDING AND RESIGHTING

INTRODUCTION

Long-term monitoring of willow flycatchers of known identity, sex, and age is the only effective way to determine demographic life history parameters such as annual survivorship of adults and young, site fidelity, seasonal and between-year movements, and population structure. Thus, as an integral part of our studies, we captured and uniquely color-banded as many willow flycatchers as possible, allowing field personnel to resight individuals throughout the breeding season, as well as in subsequent years. Resighting consisted of using binoculars to determine the identity of a color-banded flycatcher by observing, from a distance, the unique color combination on its legs. This allowed field personnel to detect and monitor individuals without recapturing each bird. This was our seventh consecutive year of color-banding studies and builds upon color-banding initiated at these sites in 1997 (McKernan and Braden 1998).

METHODS

Color-banding

From early May through mid-August, we captured, uniquely color-banded, and subsequently monitored adult and nestling willow flycatchers at all study areas where resident willow flycatchers were detected. The color-banding effort also included opportunistic banding at Key Pittman Wildlife Management Area in Nevada (in cooperation with Nevada Division of Wildlife) and in St. George, Utah (in cooperation with Utah Division of Wildlife Resources).

Adult flycatchers were captured with mist-nets, which provide the most effective technique for live-capture of adult songbirds (Ralph et al. 1993). We used a targeted capture technique (per Sogge et al. 2001), whereby a variety of conspecific vocalizations were broadcast from a CD player and remote speakers to lure territorial flycatchers into the nets. In addition, we used "passive netting," whereby several mist-nets were erected and periodically checked, with no broadcast of conspecific vocalizations. We banded each adult willow flycatcher with a single, numbered U.S. federal aluminum band on one leg and a colored metal band on the other. We coordinated all color combinations with the Federal Bird Banding Laboratory and all other Southwestern Willow Flycatcher banding projects to minimize replication of color combinations. For each color-banded bird recaptured, we visually inspected the legs and noted any evidence of irritation or injury that may be related to the presence of leg bands.

Nestlings were banded at 8 to 10 days of age, when they were large enough to retain the leg bands, yet young enough that they would not prematurely fledge from the nest (Whitfield 1990, Paxton et al. 1997). Nestlings were banded only when the location of the nest was such that nest access and removal/replacement of the nestlings would not endanger the nest, nest plant, or nestlings. Nestlings were also banded with a single, numbered federal band on one leg and a metal color-band on the other leg. Prior to 2008, we banded each nestling only with a single federal band, identifying it as a returning nestling in the event it returned in a subsequent year.

For each captured adult willow flycatcher, we recorded morphological measurements including culmen, tail, wing, fat level, and molt onto standardized data forms (Appendix A). Sex was determined based on

the presence of a cloacal protuberance in males or brood patch and/or egg(s) in the oviduct for females. Captured flycatchers lacking breeding characteristics and not observed engaging in male advertising song (see below) were sexed as unknown. Flycatchers with retained primary, secondary, and/or primary covert feathers (multiple aged remiges) were aged as second year adults, and those without (uniformly aged remiges) were aged as after second year (per Kenwood and Paxton 2001 and Koronkiewicz et al. 2002). Individuals in juvenile plumage (unworn flight feathers and body plumage with broad, buff colored wing bars and fleshy gape) were aged as hatch year.

Resighting

We determined the identity of a color-banded flycatcher by observing with binoculars, from a distance, the unique color combination on its legs. Typically, territories and active nests were focal areas for resighting, but entire sites were surveyed. Field personnel typically spent the early part of each morning color-banding, and directed their efforts to resighting as daylight increased and flycatchers became more difficult to capture. All banding, monitoring, and survey field personnel coordinated resighting efforts and recorded observations of color-banded and unbanded flycatchers onto standardized data forms (Appendix A). For resighted flycatchers (i.e., one for which at least one leg was seen clearly enough to determine the presence or absence of a band), we recorded color-band combinations, territory number, site, standardized confidence levels of the resight, and behavioral observations. Willow flycatchers for which detections spanned one week or longer were considered resident at a site, regardless of the portion of the breeding season in which the bird was observed or whether a possible mate was observed. Flycatchers observed engaging in lengthy, primary song from high perches (male advertising song) were sexed as male, and flycatchers observed carrying nest material or constructing or incubating a nest were sexed as female. Flycatchers not observed engaging in one of these diagnostic activities were sexed as unknown.

Inactive territories were visited at least three times (each visit four days apart) before territory visits stopped. All territories were assigned a unique alphanumeric code and were plotted onto high-resolution aerial photographs, thus producing a spatial representation of the flycatcher population at each study location. Flycatchers were determined to be unpaired if none of the following breeding behaviors were observed: presence of another unchallenged flycatcher in the immediate vicinity, counter calling (***whitts***) with a nearby flycatcher, interaction twitter calls (***churr/kitters***) with a nearby flycatcher, a flycatcher in the immediate vicinity carrying nesting material, a flycatcher in the immediate vicinity carrying food or fecal sac, or adult flycatchers feeding young (per Sogge et al. 1997).

Unbanded flycatchers could not be identified to individual, but an unbanded flycatcher detected in a given location on multiple, consecutive visits was assumed to be the same individual. If an unbanded flycatcher was detected at a given location on multiple visits but one or more intervening visits failed to detect a flycatcher, the detections were considered to be different individuals in the absence of behavioral observations indicating the flycatcher was actively defending a territory or was a member of a breeding pair.

RESULTS

All Monitoring Sites

Color-Banding and Resighting – Field personnel color-banded 17 new adult flycatchers and recaptured 8 individuals previously captured as adults. An additional 55 adults were identified to individual via resighting, while 10 individuals were resighted but did not have their color combinations confirmed.

One adult had federal band on one leg and an injury on the other leg, and one adult had a duplicate color-band combination. We detected eight individuals identified as returning nestlings by the presence of a single federal band, with three (38%) identified to individual via recapture. Thirty-one adult flycatchers remained unbanded, and banding status was undetermined (i.e., we were unable to determine if these individuals were banded) for 19 adults. Overall, 67% of the adult flycatchers detected at the monitoring sites were known to be color-banded by the end of the breeding season (Table 3.1). We banded 44 nestlings from 21 nests. Of the 44 nestlings banded, 5 were known or suspected to have died before fledging. For details on all banded flycatchers detected at the study areas from 2003 to 2009, see Appendix D.

Site-by-Site Color-Banding and Resighting

Monitoring Sites

Pahranagat – We detected 21 resident, adult willow flycatchers from 12 territories at Pahranagat. In addition to resident adults, we detected three individuals for which residency and/or breeding status could not be confirmed (Table 3.2). Of the 12 territories recorded at Pahranagat, 10 consisted of breeding pairs and 2 consisted of unpaired males. Of the breeding individuals, one male was polygynous with two females, and one female mated consecutively with two males.

Field personnel captured and color-banded five new adults and recaptured six flycatchers previously captured as an adult. We resighted and confirmed band combinations for an additional 11 adults. Of the resighted adults, one was originally banded as a nestling in 2008 (see Table 3.6 for juvenile dispersal data). The presence of bands could not be determined for two adults. We banded 11 nestlings from five nests, and 2 of these nestlings were recaptured as fledglings. We resighted 13 unbanded fledglings from four additional nests.

Littlefield – We detected four resident, adult willow flycatchers from three territories at Littlefield. In addition to resident adults, we detected one individual for which residency and/or breeding status could not be confirmed (Table 3.2). Of the three territories, two consisted of breeding pairs and one consisted of an unpaired male. Of the breeding individuals, one male was polygynous with two females.

Field personnel captured and color-banded one new adult. We resighted and confirmed band combinations for an additional adult, which was originally banded as a nestling in 2008 (see Table 3.6). One resident adult remained unbanded, and band status could not be determined for another. Band status also could not be determined for the individual for which residency and/or breeding status could not be confirmed.

Mesquite – We detected 25 resident, adult willow flycatchers from 15 territories at Mesquite. In addition to resident adults, we detected three individuals for which residency and/or breeding status could not be determined. Of the 15 territories recorded at Mesquite, 12 consisted of paired individuals and 3 consisted of unpaired males (Table 3.2). Of the breeding individuals, two males were polygynous with two females and one female mated consecutively with two males.

Field personnel recaptured two flycatchers previously captured as adults. We confirmed the identities of an additional 14 adults via resighting. One additional adult had a federal band on one leg and an injury on the opposite leg, and another adult had a duplicate color combination. Of the resighted adults, three were originally banded as nestlings in 2008 (see Table 3.6). Eight adults remained unbanded, and three adults were banded but band combinations could not be confirmed. We banded four nestlings from four nests.

Mormon Mesa – We detected 27 resident, adult willow flycatchers from 17 territories at Mormon Mesa. In addition to resident adults, we detected six individuals for which residency could not be confirmed (Table 3.2). Of the 17 territories recorded at Mormon Mesa, 13 consisted of breeding individuals and 4 consisted of unpaired males. Of the breeding individuals, three males were each polygynous with two females.

Field personnel captured and color-banded two new adults. We resighted and identified 21 additional returning adults; of these, five were banded as nestlings in 2008 (see Table 3.6). We captured one returning nestling originally banded as a juvenile in 2007 and resighted one additional returning nestling with a single federal band that we were unable to recapture. Four adults remained unbanded, and band combinations could not be confirmed for four adults. We banded 22 nestlings from nine nests. Three of these nestlings were known to have died before fledging. We resighted three unbanded fledglings from three nests.

Muddy River – We detected 13 resident, adult willow flycatchers from eight territories at Muddy River. In addition to resident adults, we detected four individuals for which residency could not be confirmed. Of the eight territories recorded, six consisted of breeding individuals and two consisted of unpaired males (Table 3.2). Of the resident individuals, one female mated consecutively with two males, both of which were consecutively mated with two females.

Field personnel captured and color-banded two new adults. We resighted and identified four other adults, three of which were banded as nestlings in 2008 (see Table 3.6). We resighted one adult for which the band combination could not be confirmed. We resighted two returning nestlings with single federal bands but could not capture these individuals to determine year and study area of origin. Seven adults remained unbanded, and band status could not be determined for one individual. We banded one nestling, which died before fledging.

Topock – We detected 14 resident, adult willow flycatchers from 13 territories at Topock. In addition to resident adults, we detected 14 individuals for which residency and/or breeding status could not be confirmed (Table 3.2). Of the 13 territories recorded at Topock, 1 consisted of paired individuals, 8 consisted of unpaired males, and 1 contained an individual for which gender could not be determined. In each of the remaining three territories, a singing male was detected throughout the breeding season and an unchallenged flycatcher, suspected to be a female, was detected for only a few days in June.

Field personnel captured and color-banded one new adult and resighted and identified two other banded adults. We captured two returning nestlings originally banded in 2007 (see Table 3.6) and resighted but were unable to recapture two additional returning nestlings with single federal bands. Seven adults remained unbanded, and the band status of 12 individuals could not be determined. The color combinations of two banded adults could not be confirmed. We banded three nestlings from one nest.

Table 3.1. Summary of Willow Flycatchers Detected at Monitored Sites during the 2009 Breeding Season*

Study Area	Site	Adults									Nestlings Banded (# nests)	Fledglings Captured	% of All Adults Banded

* Individuals are identified as new captures (previously unbanded), recaptures of previously banded birds, resightings of previously banded birds for which band combinations were confirmed, birds known to be unbanded, birds for which band status could not be determined, and resighting of previously banded birds for which band combinations were undetermined. Included are total numbers of adults detected and percent of all adults banded. For breeding and/or residency status of adults see Table 3.2.

[1] Both individuals banded as nestlings and recaptured as fledglings.

[2] One individual had silver federal band only and had a visible injury on the unbanded left leg; a male with silver federal band number 2390-92434 and a visible injury on the unbanded left leg was captured at Mesquite in 2005, and this is likely the same individual. Other individual had a duplicate color combination.

[3] Returning nestling(s).

Table 3.2. Willow Flycatchers Detected at All Monitored Study Areas with Resident Flycatchers, 2009 (Continued)

[1] PAHR = Pahranagat NWR, LIFI = Littlefield, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR.

[2] N/A = not applicable, INA = information not available.

[3] **Color-band codes**: EE = electric yellow federal band, PU = pumpkin federal band, Bs = blue federal band, XX = standard silver federal band, TQ = turquoise federal band, (M) = metal pin striped band, UB = unbanded, R = red, O = orange, Y = yellow, G = green, D = dark blue, B = light blue, V = violet, W = white, K = black, Z = gold, banded = bird was banded but combination could not be determined, undetermined = presence of bands could not be determined. Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band; color-band designations for right and left legs are separated with a colon.

[4] Old combination included only if rebanded in 2009.

[5] **Age in 2009**: L = nestling, HY = hatch year, SY = 2 years, AHY = 2 years or older, 3Y = 3 years, A3Y = 3 years or older, 4Y = 4 years, A4Y = 4 years or older, etc.

[6] **Sex codes**: M = male, F = female, U = unknown.

[7] **Territory or Location code**: Number without an alpha code indicates a flycatcher pair, T = territorial individual detected for at least 7 days, F = individual detected for less than 7 days. Number indicates unique location.

[8] **Observation status codes**: N = new capture, R = recapture followed by date recaptured, RS = resight.

[9] Right leg injured, but color-band could not be removed.

[10] Nestling suspected to have died before fledging.

[11] This federal band removed.

[12] Female mated consecutively with two different males.

[13] Band number likely 2390-92434 but cannot be confirmed because bird was not captured in 2009. Bird had visible injury on left leg.

[14] Color combination is a duplicate; federal band number and identity of flycatcher unknown.

[15] Right leg not banded because of pre-existing injury.

[16] Fledgling found dead near nest.

[17] Nestling died before fledging.

[18] Original federal band 2370-40173.

[19] Recapture on 15 May was in a passive net at the Beal Lake MAPS station.

Bill Williams – We detected 13 resident willow flycatchers from eight territories at Bill Williams. In addition to resident adults, we detected two individuals for which residency and/or breeding status could not be determined (Table 3.2). Of the eight territories recorded at Bill Williams, five consisted of paired individuals and two consisted of unpaired males. In the remaining territory a singing male was detected through most of June, and an unchallenged flycatcher, suspected to be a female, was detected for only a few days in June.

Field personnel captured and color-banded six new adults. We resighted and identified three returning banded adults. Four adults remained unbanded, and band status could not be determined for two adults. We banded three nestlings from one nest and resighted three unbanded fledglings from another nest.

Non-Monitoring Sites

These study areas were monitored by other agencies, and here we report only banded flycatchers that were captured or resighted. Unbanded individuals or those with unknown band status are not included.

Key Pittman Wildlife Management Area – Field personnel captured and color-banded two new adults (Table 3.3). We resighted and identified four returning banded adults. We banded seven nestlings from three nests.

St. George – Field personnel captured and color-banded four new adults. We resighted and identified two adult flycatchers, one of which was banded as a nestling in 2008. We recaptured another adult that was banded as a nestling in 2001 and had not been identified since. Another adult was identified as a returning nestling, but we were unable to capture this individual to determine year and study area of origin. We banded five nestlings from two nests; four of these died before fledging (Table 3.3).

[1] KEPI = Key Pittman Wildlife Management Area, STGE = St. George.

[2] **Color-band codes**: EE = electric yellow federal band, PU = pumpkin federal band, TQ = turquoise federal band, XX = standard silver federal band, (M) = metal pin striped band, UB = unbanded, R = red, O = orange, Y = yellow, G = green, D = dark blue, B = light blue, V = violet, W = white, K = black, Z = gold. Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band; color-band designations for right and left legs are separated with a colon.

[3] Old combination included only if rebanded in 2009.

[4] **Age in 2009:** L = nestling, SY = 2 years, AHY = 2 years or older, 3Y = 3 years, A3Y = 3 years or older, 4Y = 4 years, A4Y = 4 years or older, etc.

[5] **Sex codes**: M = male, F = female, U = unknown.

[6] **Observation status codes**: N = new capture, R = recapture followed by date recaptured, RS = resight.

[7] Original federal band number 2140-66690.

[8] Nestling died before fledging.

Adult Between-Year Return and Dispersal

In 2008 we individually identified 75 adult, resident willow flycatchers at our monitored study areas, of which 41 (55%) were detected in 2009 (Table 3.4). Of the returning resident adults, one (2%) was detected at a different study area than where it was last detected in 2008 (Table 3.5). One adult flycatcher that was detected in 2008 but not confirmed to be a resident was detected at a different study area in 2009. Two flycatchers that were banded in 2008 at study areas monitored by other agencies were detected at our monitored study areas in 2009. One additional adult, which was last detected in 2006, exhibited between-year movement in 2009. The median dispersal distance for all returning adult flycatchers exhibiting between-year movements in 2009 was 29.1 km (min = 26.9 km, max = 70.2 km).

Table 3.4. Resident Adult Willow Flycatcher Annual Return from 2008 to 2009

Study Area	# Identified in 2008	# of 2008 Birds Detected in 2009	% Return	% Return to Same Study Area

[1] PAHR = Pahranagat NWR, KEPI = Key Pittman WMA, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, LVWA = Las Vegas Wash.

[2] **Color-band codes**: EE = electric yellow federal band, PU = pumpkin federal band, XX = standard silver federal band, (M) = metal pin striped band, R = red, Y = yellow, G = green, D = dark blue, B = light blue, V = violet, W = white, K = black, Z = gold. . Color combinations are read as the bird's left leg and right leg, top to bottom; two letters designate every band; color-band designations for right and left legs are separated with a colon.

[3] **Sex codes**: F = female, M = male.

[4] This individual was at Pahranagat North through 11 Jul but was detected at Key Pittman on 26 Jul 2008.

Juvenile Between-Year Return and Dispersal

In 2008, we banded 74 nestlings at the monitored study areas. One of these nestlings was known to have died before fledging. Of the 73 remaining juveniles, 12 (16%) were identified in 2009. Two additional flycatchers banded as nestlings in St. George in 2008 were identified in 2009. Three individuals originally banded as nestlings in 2007 were identified for the first time in 2009, and one individual banded as a nestling in 2001 was identified breeding in St. George (Table 3.6). Of the 18 returning nestlings identified in 2009, 10 (56%) dispersed away from their natal study area. The median dispersal distance for all returning juvenile flycatchers in 2009 was 13.7 km (min = 0.03 km, max = 202.8 km).

[2] **Color-band codes**: PU = pumpkin federal band, XX = standard silver federal band, (M) = metal pin striped band, R = red, O = orange, G = green, B = light blue, D = dark blue, V = violet, W = white, Y = yellow, K = black. Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band; color-band designations for right and left legs are separated with a colon.

[3] **Sex codes**: F = female, M = male, U = unknown.

Five additional returning nestlings from 2003–2007 were resighted in 2009 (one at Mormon Mesa, two at Muddy River, and two at Topock), but the identity of these individuals was undetermined because we were unable to recapture them.

Within-Year, Between-Study Area Movements

We detected no within-year, between-study area movements in 2009.

DISCUSSION

Color-Banding Effort

Overall, 67% of the adult flycatchers detected at the monitoring sites during 2009 were banded by the end of the breeding season. This compares to 55, 57, 75, 70, 73, and 69% in 2003–2008, respectively.

Unbanded migrant willow flycatchers are included in calculating these percentages; therefore, in most cases, these numbers under-represent the actual proportion of resident banded flycatchers at a given site. We have maintained high overall percentages of banded birds annually over the seven years, which has enabled us to detect movements, generate dispersal data, and determine survival and detection probabilities across study areas (McLeod et al. 2008). Differences between study areas in the percentage of banded individuals are directly related to vegetation density and overall structure, which affect our ability to erect mist-nets in the habitat. Topock Marsh typically has the lowest percentage of color-banded flycatchers because dense vegetation limits the number and size of possible net locations.

Prior to 2008, we banded all nestlings with a single anodized federal band, identifying the bird as a returning nestling in the event it was sighted in a subsequent year. The individual would then have to be recaptured to determine its individual identity and to apply a unique color combination so the bird could be individually identified via resighting. Returning nestlings are particularly difficult to recapture at Topock. The rationale for banding nestlings with a single anodized band was that the majority of nestlings do not return in subsequent years, resulting in the loss of a large number of unique color combinations. To eliminate the need to recapture returning nestlings, in 2008–2009 we applied unique color combinations to all nestlings. The use of full color combinations on nestlings in 2008 resulted in approximately half as many adults with single federal bands being detected in 2009 than in previous years. Additionally, we recorded juvenile dispersal movements that might otherwise have gone undetected. Although a large number (118) of unique color combinations were used on nestlings in 2008–2009, the benefits in terms of high resolution demographic data outweigh the loss of unique color combinations.

Adult and Juvenile Between-Year Dispersal

Adult and juvenile dispersal data for the 2009 field season show high site fidelity exhibited by adult flycatchers and lower natal site fidelity exhibited by juveniles, with juveniles dispersing among study areas annually. These dispersal data are consistent with the patterns observed in the LCR region from 1998 to 2009, over which period 92% of adult returns were to the same study area while only 55% of all juvenile returns were to the natal study area (McKernan and Braden unpubl. data, McLeod et al. 2008, McLeod and Koronkiewicz 2009). These dispersal data are also consistent with range-wide data (Paxton et al. 2007), with adult flycatchers exhibiting high site fidelity to breeding areas. Juvenile dispersal within the Virgin/lower Colorado River population(s) is largely limited to this region, and while reciprocal juvenile movements among geographically isolated flycatcher populations of the greater Southwest do occur, they are rare. Only three instances of willow flycatcher immigration from sites outside the Virgin/lower Colorado River region have been recorded since 1997 (McKernan and Braden unpubl. data, McLeod et al. 2008), with two males originally banded as nestlings in 2003 at Roosevelt Lake recaptured in 2005 at Muddy River and Topock, and one male banded as a nestling in 1999 at Roosevelt Lake recaptured in 2002 in Grand Canyon. Although movements of this magnitude are infrequent, other instances of dispersal distances greater than 140 km have been reported for the Southwestern Willow Flycatcher (Paxton et al. 2007).

The observed dispersal patterns fit well with the tenets of contemporary metapopulation theory (Hanski and Simberloff 1997), suggesting the Virgin/lower Colorado River population may be a panmictic sub-population of a greater metapopulation. Occasional juvenile dispersal between sub-populations is likely an important population variable in terms of both gene flow and possibly the establishment of new flycatcher populations. These juvenile movements contribute to an understanding of the observed patterns of high genetic diversity within and low genetic isolation among Southwestern Willow Flycatcher populations (Busch et al. 2000). Physical connectivity of riparian habitats within the greater landscape is crucial in enabling these long-distance movements. Without adequate stop-over habitats and

foraging areas, flycatchers attempting long-distance movements are more likely to be exposed to adverse environmental conditions.

Adult and Juvenile Survivorship

Annual survivorship is defined as the number of individuals that survive from one year to the next, and accurate estimates depend on year-to-year detection of uniquely marked birds. Fifty-five percent of the adult, resident willow flycatchers identified in 2008 were detected again in 2009, while of the 73 juveniles banded in 2008, only 12 (16%) were identified in 2009. Thus, minimum estimated adult and juvenile survival from 2008 to 2009 was 55 and 16%, respectively. These simple annual percent survivorship calculations assume that all living flycatchers are detected in a given year, and individuals not detected are assumed to have died, unless detected elsewhere. To provide more robust estimates of annual survival, demographic data acquired from 2003 to 2012 will be combined with data collected during 1997–2002. Survival and detection probabilities will be estimated using program MARK (White and Burnham 1999) and presented in a summary report in 2012.

Chapter 4

NEST MONITORING

INTRODUCTION

Documentation of nest success and productivity is critical to understanding local population status and demographic patterns of the Southwestern Willow Flycatcher. In 2009, at all sites where willow flycatcher breeding activity was suspected, we conducted intensive nest searches and nest monitoring. Specific objectives of nest monitoring included identifying breeding individuals (see Chapter 3, Color-banding and Resighting), calculating nest success and failure, documenting causes of nest failure (e.g., abandonment, desertion, depredation, and brood parasitism), and calculating nest productivity. Nest monitoring results from 2009 were compared with those at the study areas from 1996 to 2008 (Braden and McKernan unpubl. data, McLeod et al. 2008, McLeod and Koronkiewicz 2009). Although aspects of willow flycatcher breeding ecology can vary widely across its broad geographical and elevational ranges throughout the Southwest (Whitfield et al. 2003), we compared monitoring results with range-wide data to identify specific variables that may contribute to the characterization of flycatcher breeding ecology throughout the lower Colorado and Virgin River riparian systems.

METHODS

Upon locating territorial willow flycatchers, regardless of whether a possible mate was observed, we conducted intensive nest searches following the methods of Rourke et al. (1999). Nest monitoring followed a modification of the methods described by Rourke et al. (1999) and the Breeding Biology Research and Monitoring Database (BBIRD) protocol by Martin et al. (1997).

Nests were located primarily by observing adult flycatchers return to a nest or by systematically searching suspected nest sites. Nests were monitored every two to four days after nest building was complete and incubation was confirmed. During incubation and after hatching, nest contents were observed directly using a telescoping mirror pole to determine nest contents and transition dates. Nest monitoring during nest building and egg laying stages was limited to reduce the chance of abandonment during these periods. To reduce the risk of depredation (Martin et al. 1997), brood parasitism by the Brown-headed Cowbird, and premature fledging of young (Rourke et al. 1999), we observed nests from a distance with binoculars once the number and age of nestlings were confirmed. If no activity was observed at a previously occupied nest, the nest was checked directly to determine nest contents and cause of failure. If no activity was observed at a nest close to or on the estimated fledge date, we conducted a systematic search of the area to locate possible fledglings.

Per instructions from Reclamation biologists, we considered a willow flycatcher nest successful only if fledglings were observed near the nest or in surrounding areas. The number of young fledged from each nest was counted based on the number of fledglings actually observed. This method of determining success differs from that recommended by some nest monitoring protocols (e.g., Martin et al. 1997, Rourke et al. 1999), which consider a nest as successful if chicks are observed in the nest within two days of the estimated fledge date. The method we follow produces a conservative estimate of both nest success rate and number of fledges.

We considered a nest to have failed if (1) the nest was abandoned prior to egg laying (abandoned); (2) the nest was deserted with flycatcher eggs or young remaining (deserted); (3) the nest was found empty or

destroyed more than two days prior to the estimated fledge date (depredated); (4) the nest was destroyed due to weather (weather); or (5) the entire clutch was incubated for an excess of 20 days (infertile/addled). For nests containing flycatcher eggs, parasitism was considered the cause of nest failure if (1) cowbird young outlived any flycatcher eggs or young, or (2) the nest was parasitized during egg laying and the disappearance of flycatcher eggs coincided with the appearance of cowbird eggs.

During each nest check, we recorded date and time of the visit, observer initials, monitoring method (observation via binoculars or mirror pole), nesting stage, nest contents, and number and behavior of adults and/or fledges present onto standardized data forms (Appendix A) that included the nest or territory number and UTM coordinates. We calculated flycatcher nest success using both apparent nesting success (number of successful nests/total number of nests containing at least one flycatcher egg) and the Mayfield method (Mayfield 1961, 1975), which calculates daily nest survival to account for nests that failed before they were found. We assumed one egg was laid per day, and incubation was considered to start the day the last egg was laid (per Martin et al. 1997). The nestling period was considered to start the day the first egg hatched and end the day the first nestling fledged. If exact transition dates or dates of depredation events were unknown, we estimated the transition date as halfway between observations. For nests where fate was unknown, we used the last known date of activity to determine the number of observation days. To calculate Mayfield survival probabilities (MSP), we used the average length of each nest stage (2.12, 12.86, and 13.75 days for laying, incubation, and nestling stages, respectively) as observed in this study in 2003–2009 for nests where transition dates were known. Nest productivity was calculated as the number of young fledged per nesting attempt that produced at least one flycatcher egg. Fecundity was calculated as number of young produced per female over the breeding season. Parasitism rates were calculated as the percentage of nests with known contents that included at least one flycatcher egg and one cowbird egg.

RESULTS

Nest Monitoring

We documented 72 willow flycatcher nesting attempts at Pahranagat, Littlefield, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams; 65 of these nests were known to contain flycatcher eggs and were used in calculating nest success and productivity. Twenty-three (35%) nests were successful and fledged young, 40 (62%) failed, and fate was unknown for 2 (3%). Nest success ranged from 0% at Littlefield and Muddy River to 53% at Mormon Mesa (Table 4.1). For a comparison of apparent nest success at all monitoring sites from 1997 to 2009, see Table 4.2.

Forty-eight nesting females, of which all but three were known to have produced at least one egg, were followed through all of their nesting attempts. One additional female was detected for which no nesting attempt could be confirmed. Of the 48 nesting females, 26 had one nesting attempt, 21 had two nesting attempts, and 1 had four nesting attempts. Of the 22 females with multiple nesting attempts, 19 renested after failed nests and 3 renested after successful nests.

* Data from 1997 to 2002 are from Braden and McKernan (unpubl. data); these numbers have been verified with the raw data and may differ from those presented in earlier annual reports. Data from 2003 to 2007 are from McLeod et al. 2008, data from 2008 are in McLeod and Koronkiewicz 2009, and data from 2009 are in this document. Data are presented as percent apparent nest success with total number of nests containing at least one flycatcher egg indicated in parentheses.

[1] Study area includes the Mesquite East, Mesquite West, and Bunker Farm sites.

[2] Study area includes the Virgin River Delta at Lake Mead.

[3] Study area not monitored.

[4] Study area surveyed, no breeding documented.

[5] Breeding suspected, nest success not calculated.

[6] Breeding confirmed, nest success not calculated.

[7] Breeding confirmed, undetermined if nestlings from a single nest fledged.

[8] An additional three nests (18%) were suspected to have fledged but fledglings were not visually confirmed.

[9] Fate of one nest was unknown.

Nest Failure

Depredation was the major cause of nest failure, accounting for 40% (19 of 47) of all failed nests (Table 4.3) and 48% (19 of 40) of nests that failed after flycatcher eggs were laid. Seven nesting attempts (15% of all failed nests) were abandoned prior to willow flycatcher eggs being laid, and 10 nests (21%) were deserted. Six nests (13%) failed because of Brown-headed Cowbird parasitism (see below for more details on parasitism).

Table 4.3. Summary of Causes of Willow Flycatcher Nest Failure at Pahranagat, Littlefield, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams Study Areas, 2009*

Total	**72**	**47**	**7 (15)**	**10 (21)**	**19 (40)**	**6 (13)**	**2 (4)**	**3 (6)**

* All nesting attempts (those with and without flycatcher eggs) are included. Percentage of failed nests is shown in parentheses for each cause of failure.

[1] PAHR = Pahranagat NWR, LIFI = Littlefield, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR.

[2] Nests were too high to use a mirror pole; depredation likely.

[3] One nest deserted after 14 days incubation, one deserted after 16 days incubation, one nest already deserted when found with one flycatcher egg and one cowbird egg, one nest deserted after partial depredation.

[4] One nest deserted with nestlings, one deserted after 16 days incubation, one deserted after partial depredation.

[5] One nest deserted after being parasitized, one deserted after partial depredation.

[6] Nest deserted after 17 days incubation.

Brood Parasitism

Sixteen of 56[1] nests (17%) with flycatcher eggs and known contents were brood parasitized by Brown-headed Cowbirds (Table 4.4). For nests containing flycatcher eggs, parasitism caused nest failure at six nests. In four of these cases, the parasitism event coincided with the disappearance of all flycatcher eggs. One nest fledged a cowbird, and another likely fledged a cowbird although the fledgling could not be located. In both of these cases, the one flycatcher egg remaining after the parasitism event did not hatch. Two parasitized nests (13%) successfully fledged at least one flycatcher. Of the remaining six parasitized nests that contained flycatcher eggs, three were deserted, three were depredated, one contained addled eggs, and one had unknown fate. Brood parasitism ranged from 0 to 100% and was highest at Littlefield (see Table 4.1). In 2009, nests that contained flycatcher eggs and were brood parasitized were less likely to fledge flycatcher young than nests that were not parasitized (Chi-square = 3.93, $P = 0.047$).

Table 4.4. Fates of Willow Flycatcher Nests Parasitized by Brown-Headed Cowbirds, 2009*

Study Area[1]	Nest ID Code	Outcome[2]
LIFI	20A	Probably fledged a cowbird, but fledging not confirmed. WE did not hatch
	105A	Abandoned with one CE
MESQ	7A	Depredated with two WE and one cowbird nestling
	7B	Abandoned with three CE
	24B	Fledged one flycatcher and one cowbird
	39A	Found deserted with one WE and one CE
	43A	Deserted after partial depredation reduced nest contents from three WE and one CE to one WE and one CE
	43B	Depredated during incubation
	44A	Parasitized during incubation; all three WE disappeared, one CE appeared
	44B	Nest fate unknown; possibly fledged one flycatcher
MUDD	10A	All eggs addled; deserted after 21 days incubation with two CE and one WE
	16A	Parasitized during incubation; both WE disappeared and two CE appeared
	18A	Depredated during nestling period; possibly fledged a cowbird prior to flycatcher nestling being depredated, but no fledgling seen
	38A	Deserted during incubation after parasitism changed clutch from three WE to one WE and two CE
	38B	Parasitized during incubation; all three WE disappeared and one CE appeared
	51B	Parasitized during incubation; all three WE disappeared and one CE appeared
BIWI	46A	Fledged three flycatchers; CE did not hatch
	61B	Fledged one cowbird; WE did not hatch

* All nesting attempts are included.

[1] LIFI = Littlefield, MESQ = Mesquite, MUDD = Muddy River, BIWI = Bill Williams River NWR.

[2] WE = willow flycatcher egg, CE = cowbird egg.

[1] Table 4.1 shows a total of 65 nests known to contain at least one flycatcher egg. When calculating brood parasitism rates, however, nine nests whose contents could not be determined were excluded from calculations (i.e., nests that were too high to check contents to determine presence/absence of cowbird eggs).

Mayfield Nest Success and Nest Productivity

Mayfield survival probability (MSP) ranged from 0.053 at Muddy River to 0.519 at Topock and was 0.368 for all sites combined (Table 4.5). At all sites, 56 nestlings were confirmed to have fledged from 63 nests of known outcome (mean number of fledglings/nest = 0.89, SE = 0.16). Fecundity across study areas ranged from 0 to 3.00 young per female and averaged 1.14 (SE = 0.21) (Table 4.6).

Table 4.5. Daily Survival Rates and Mayfield Survival Probabilities (MSP) for Willow Flycatcher Nest Stages at Pahranagat, Littlefield, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams Study Areas, 2009*

Study Area	Nest Stage[1]	Nest Losses/ Observation Days	Daily Survival Rate	Mayfield Survival Probability
Pahranagat	1	0/23	1.000	1.000
	2	7/134	0.948	0.502

	MSP all stages = 0.368			

* Mayfield survival probability was calculated using 2.12-day egg laying, 12.86-day incubation, and 13.75-day nestling stages.

[1] 1 = egg laying, 2 = incubation, 3 = nestling.

Table 4.6. Willow Flycatcher Nest Productivity (Young Fledged per Nest) and Fecundity (Young Fledged per Female) at Pahranagat, Littlefield, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams Study Areas, 2009*

Study Area	Young Fledged	# Nests	Productivity Mean (SE)	# Females	Fecundity Mean (SE)
Pahranagat	22	16	1.38 (0.38)	10	2.20 (0.42)
Littlefield	0	1	0	2	0 (0)
Mesquite	3	13	0.23 (0.12)	12	0.25 (0.18)
Mormon Mesa	22	17	1.45 (0.35)	13	1.69 (0.44)
Muddy River	0	8	0 (0)	6	0 (0)
Topock	3	2	1.50 (0.38)	1	3.00
Bill Williams	6	6	1.00 (0.63)	5	1.20 (0.73)
Total	**56**	**63**	**0.89 (0.16)**	**49**	**1.14 (0.21)**

* Productivity calculations include nests that contained flycatcher eggs and had a known outcome. Fecundity calculations include all females, and nests with unknown outcome are assumed not to have fledged, thus producing a conservative fecundity estimate.

DISCUSSION

In 2009, willow flycatcher nesting was documented at Pahranagat, Littlefield, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams. The number of flycatcher pairs recorded at Pahranagat, Mesquite, and Mormon Mesa was nearly identical to that recorded in 2008. Bill Williams and Muddy River both had six pairs in 2009 versus four in 2008. Breeding was recorded at Littlefield for the first time since 2004. Given that southwestern riparian ecosystems experience dynamic change and are not ecologically static (Periman and Kelly 2000), willow flycatcher occupancy and nesting are likely to be affected by changes in habitat suitability, with breeding flycatchers detected at a given site in one year and not in another.

Topock Marsh had 14 resident flycatchers, which consisted of 12 unpaired individuals and only one breeding pair, the lowest number of breeding pairs recorded since monitoring began in 1997. In three other territories at Topock, we detected a second flycatcher in addition to the territorial male. In each case, the additional flycatcher was detected for less than one week and suspected to be female, based on interactions with the male and lack of defensive behavior on the part of the male. Gender was not confirmed, however, and no breeding activity was detected. The three suspected females are not included in calculations of fecundity.

Female willow flycatchers are more discriminating in habitat selection than males, with females having to choose habitat conducive to the complexities of nesting (e.g., concealment, microclimate requirements) versus choosing habitat favorable to male advertising and territory defense (Sedgwick and Knopf 1992). Willow flycatcher nest sites at study areas in the LCR region differed from within-territory locations in several vegetation and microclimate variables, suggesting that females are discriminating among potential nest sites on a very local scale (McLeod et al. 2008). Thus, the male skew in the sex ratio of residents at Topock and presence of suspected non-breeding, floater females may be indicative of poor breeding habitat quality. A similar pattern was observed at Roosevelt Lake, Arizona, during the severe drought of 2002, when declines in vegetation vigor and prey availability dramatically decreased female nesting behavior, resulting in almost complete reproductive failure (Paxton et al. 2007). Males arrived in May and set up territories, but the majority of females detected were floaters, did not nest, or abandoned nests before they were complete (E.H. Paxton pers. comm.). Whether other factors such as annual reproductive rates, survival, population recruitment, or other abiotic conditions contributed to reduced breeding at Topock remains unclear.

Nest Success

As in previous years, Mayfield nest success differed little (4% or less) from apparent nest success at most study areas. At Mesquite, apparent nest success (21%) was lower than Mayfield nest success (35%). The high Mayfield estimate was influenced by several nests having long incubation periods before being deserted and by one nest having an uncertain nest fate. Nests with uncertain fates are not counted as a success in apparent nest success but are not counted as a nest loss in the Mayfield estimate. The close agreement between apparent and Mayfield nest success at most study areas suggests that most nests are found early in the nesting cycle and thus relatively few nests fail before they are found.

Nest success at Pahranagat (apparent nest success = 47%, MSP = 45%), while still higher than the average for all study areas, was the lowest recorded since 2003. Nest success alone, however, is an incomplete measure of the production of young. Successful nests produce from one to four young, and variations in nest productivity are not reflected in nest success rates. In addition, although every failed nest attempt lowers percent nest success and MSP, success of a subsequent nesting attempt may result in the same number of young produced as if the initial nesting attempt had been successful. Thus, nest productivity (young produced per nesting attempt) and fecundity (young produced per female) in conjunction with nest success, provide additional information on the success of a given breeding season. Productivity at Pahranagat in 2009 (1.38 young per nest) was the lowest recorded since 2003 but did not differ significantly from that recorded in any other year (ANOVA $F_{6,93} = 0.570$, $P = 0.7530$). Fecundity (2.20 young per female) was in the middle of the range of fecundity values (1.6–3.0) recorded at the site in 2003–2009. Thus, although nest success in 2009 at Pahranagat was lower than in past years, females renested after unsuccessful first nest attempts, and fecundity did not appear to be affected.

Nest success and fecundity at Mormon Mesa were high for the second consecutive year, while productivity and fecundity at Mesquite dropped from the highest ever recorded in 2008 to the lowest recorded since 1999. Flycatchers at Muddy River experienced complete reproductive failure, as they did in 2007, and this study area has the lowest overall productivity and fecundity for any study area where breeding has been documented regularly. Nest success at Bill Williams continued to exhibit the yearly fluctuations observed since nest monitoring began in 1999. Sample sizes at Topock and Littlefield are too low to attribute much significance to the reproductive rates observed in 2009. Nest success results again illustrate that the demographic patterns of passerine populations often vary year to year, and sometimes to a very large degree (Wiens 1989a). The variable patterns of nest success observed at the study areas over many years demonstrate the need for long-term data.

Nest Failure

As in 2003–2008, depredation was the major cause of willow flycatcher nest failure, accounting for 40% of all failed nests in 2009. These results are consistent with those reported at the monitored study areas from 1998 to 2002 (Braden and McKernan unpubl. data) and at sites across Arizona from 1996 to 2008 (Graber et al. 2007, Ellis et al. 2008, Graber and Koronkiewicz 2009a), which indicate depredation as accounting for the majority of all willow flycatcher nest failures. Factors influencing the increases and decreases in nest depredation at the monitored study areas are inherently complex and at this time remain undetermined. For open-cup nesting passerines, nest depredation rates can vary year to year, and sometimes substantially, with depredation of eggs and young ultimately linked to landscape characteristics and fluctuations in predator densities, abundance, and richness (Wiens 1989b, Robinson 1992, Howlett and Stutchbury 1996).

In 2008, Northern Arizona University (NAU) initiated a nest camera study in cooperation with SWCA on open-cup nesting passerines at selected study areas (Mesquite, Pahranagat, Topock, Bill Williams) along

the lower Colorado River and tributaries. The study used video and still cameras on real and artificial nests to identify depredation rates and nest predators. Problems with both video and still cameras in 2008 affected the detection of depredation events and the identification of nest predators, but both Brown-headed Cowbirds and Yellow-breasted Chats were identified by still cameras as depredating artificial nests, and marks on clay eggs in depredated nests were consistent with these avian predators. This study was continued in 2009, with still cameras deployed at artificial nests and video cameras deployed at real nests at two flycatcher breeding areas (Pahranagat and Mesquite). Marks on clay eggs at these two study areas indicated that most depredation events at Mesquite were from birds, while at Pahranagat both birds and rodents depredated artificial nests (NAU unpubl. data). Video cameras were deployed at five flycatcher nests at Pahranagat and three at Mesquite. Of the five nests at Pahranagat, three successfully fledged flycatcher young, one was depredated during incubation by a Bewick's Wren (*Thyromanes bewickii*), and one was depredated during the nestling period by a red-shouldered hawk (*Buteo lineatus*). At Mesquite, one nest fledged one flycatcher and one cowbird, one nest was depredated during incubation by a cowbird, and the third nest was partially depredated by a cowbird during the nestling period. The cowbird removed two of three nestlings; the remaining nestling fledged successfully (NAU unpubl. data). Results of this study suggest that avian species may be important predators on flycatcher nests. Ellis et al. (2008) also identified Cooper's Hawks (*Accipiter cooperii*) and Yellow-breasted Chats depredating flycatcher nests at sites in Arizona.

Brood Parasitism

Brood parasitism by Brown-headed Cowbirds across all study areas ranged from 0 to 100% and averaged 29% (see Table 4.1). These results are consistent with those reported at the study areas from 1998 to 2007 (Braden and McKernan unpubl. data, McLeod et al. 2008, McLeod and Koronkiewicz 2009), but these parasitism rates are higher than those reported at other monitored sites across Arizona in 1996–2006, which were less than 10% at most sites in most years (Graber et al. 2007, Ellis et al. 2008).

We observed multiple occasions in which the disappearance of flycatcher eggs coincided with the parasitism event. In this case, cowbirds were suspected of ejecting the eggs. Female Brown-headed Cowbirds are known to physically attack willow flycatcher nestlings (Woodward and Stoleson 2002), remove single eggs, and occasionally destroy entire broods after laying is complete or after hatching (Lowther 1993 as cited in Woodward and Stoleson 2002). In addition, cowbirds were photographed removing eggs from artificial nests during the 2008–2009 camera study, and cowbirds were documented on video depredating flycatcher nests during both the incubation and nestling phases. Therefore, it is likely that other depredation events on eggs and nestlings are attributable to cowbirds.

Parasitism does not invariably cause nest failure, but the success rate (21%) for parasitized nests in 2003–2009 was less than half that of unparasitized nests (51%). Similar results were recorded for willow flycatchers in Oregon, with parasitism resulting in a 50% decrease in success rates compared to unparasitized nests (Sedgwick and Iko 1999) and at other sites in Arizona, where in 1996–2005, 20% of parasitized nests fledged flycatcher young vs. 57% of unparasitized nests (Ellis et al. 2008). Parasitized nests that did succeed in fledging flycatcher young at all study areas in 2003–2009 produced on average fewer young (1.3 young/nest) than did unparasitized nests (2.2 young/nest; $F_{1,183} = 18.55$, $P < 0.001$). Cowbirds may eject flycatcher eggs during the parasitism event, thus reducing clutch size, and cowbird young also cause interspecific nestling competition, as evidenced by the presence of severely underdeveloped nestlings in some parasitized nests. For all nests monitored from 2003 to 2009, 42% of nests that fledged a cowbird also fledged flycatcher young. This is a higher rate of success than that observed in Southwestern Willow Flycatchers at Kern River, California (9%; Whitfield and Sogge 1999), but comparable to that observed at other Arizona sites (40%; Ellis et al. 2008).

The inverse relationship of parasitism rates and nest success was particularly apparent at Mesquite in 2008 and 2009. In 2008, Mesquite experienced the lowest parasitism rate and highest nest success recorded at the site since 1999, and then in 2009 experienced the highest parasitism rate and lowest success rate recorded since 1999. High parasitism rates at Mesquite in 2009 may be related to changes in the habitat at Mesquite West, with dry soil conditions causing premature leaf abscission in coyote willows (see Chapter 2).

Female flycatchers may desert their nests after parasitism events and thus expend energy renesting and laying additional eggs. Given that adult flycatchers exhibit high site fidelity to breeding areas (Braden and McKernan unpubl. data, McLeod et al. 2008, McLeod and Koronkiewicz 2009, this document) and renest most often after failed nests (Sedgwick 2000), females returning to sites with high brood parasitism are likely to reduce lifetime fecundity because they are expending energy on multiple failed nesting attempts over many years. An analysis of lifetime fecundity of females will be included in the summary report in 2012. In addition, willow flycatchers that fledge late in the season have been shown to have a lower survival rate than those that fledge early in the season (Paxton et al. 2007, McLeod et al. 2008), suggesting additional hidden effects of parasitism and subsequent renesting on flycatcher demography.

Cowbird trapping and removal studies were initiated at Pahranagat, Mesquite, and Topock Marsh in 2003 and continued through 2007. Results of these studies showed that cowbird trapping appeared to lower parasitism rates in comparison to the pre-trapping period of 1998–2002 only at Pahranagat, with no parasitism detected during trapping years (McLeod et al. 2008). No cowbird trapping was completed in 2008 or 2009, but even in the absence of cowbird trapping, no parasitism events were detected at Pahranagat in either year. We did, however, regularly detect cowbirds within Pahranagat North in 2009, avoided mirror-poling nests on multiple occasions because of the presence of cowbirds, and observed other bird species feeding juvenile cowbirds. These observations suggest that although cowbird trapping may have lingering effects beyond the years in which trapping is completed, cowbirds seemed to be more numerous at Pahranagat in 2009 than in previous years.

We speculated that trapping might have affected the parasitism rate at Pahranagat but not the other study areas because Pahranagat consists of relatively small, isolated patches of riparian habitat rather than existing in a large, contiguous riparian corridor. The breeding site at Muddy River is a relatively small stand of tall trees and is bordered to the north by an extensive valley dominated by residential areas and agriculture and containing little riparian vegetation. Muddy River had 33–75% parasitism in four of the five years when flycatchers have been monitored at the study area, and overall nest success was 23%, well below the average of 45% across all study areas in those years. Although the breeding site at Muddy River is not as isolated from surrounding riparian vegetation as the site at Pahranagat, cowbird trapping at Muddy River has the possibility of reducing the parasitism rate and increasing flycatcher nest success, and we recommend that cowbird trapping be instituted at Muddy River.

In addition to cowbird trapping at Muddy River, addling cowbird eggs and/or removing cowbird eggs and young from easily accessible flycatcher nests would likely increase flycatcher nest success and productivity. We do not advise these activities at Pahranagat, which is still part of the five-year post-cowbird-trapping experiment. However, at study areas that were not part of the cowbird trapping experiment (Littlefield, Mormon Mesa, Muddy River, Bill Williams), addling eggs or removing eggs and young would not interfere with ongoing experiments and would likely benefit the flycatcher. At Mesquite and Topock, cowbird trapping was shown not to have any effect on parasitism rates and flycatcher nest success, and thus the post-trapping period will not reveal any lingering effects of trapping. Addling and/or removal of cowbird eggs and nestlings could thus be implemented at these study areas as well.

Chapter 5

VEGETATION AND HABITAT CHARACTERISTICS

INTRODUCTION

Our objective for vegetation sampling is to provide a quantitative summary of the floristic and structural conditions within occupied territories in various vegetation types. These descriptive summaries will provide guidance for managers working to restore and create riparian habitat to meet the obligations of the LCR MSCP and will provide a means to evaluate habitats to determine if they resemble occupied flycatcher territories. The Pahranagat study area was excluded from the characterization of occupied territories because the vegetation consists primarily of very large and widely spaces trees, and these characteristics are unique to the site and not likely to be replicated in restoration areas.

In addition, we investigated whether changes in vegetation characteristics might have contributed to the abandonment of some areas by flycatchers. We identified several areas that had been occupied by nesting flycatchers in at least one previous year from 2003 to 2007 but were unoccupied in 2009, and we relocated old nest sites at which we had collected vegetation information in the year the nest was active. We resampled the vegetation at these nests and compared the vegetation data collected in 2009 to that collected when the nest site was active to elucidate how changes in vegetation through time may influence flycatcher occupancy. These results will provide additional quantitative information on the characteristics of vegetation within flycatcher nesting territories.

METHODS

Currently Occupied Territories

We described and measured vegetation and habitat features following a modification of the methods of James and Shugart (1970). Vegetation characteristics were measured within a 5-m-radius circle. To avoid disrupting flycatcher breeding activities, we measured vegetation late in the summer when the nest, territory, and adjacent flycatcher territories were inactive.

In 2008, we measured vegetation and habitat characteristics at one plot for each resident (i.e., detected for at least one week) male flycatcher we identified, regardless of whether or not he obtained a mate. Plot center locations were determined as soon as territories were identified. We estimated the center of the male's activity by observing his use of singing perches and selecting a location that was approximately equidistant from the perches at the perimeter of his use area. We then proceeded in a randomly selected compass direction for a randomly selected distance between 0 and 20 m. We used additional random numbers to select the exact location in which to hang a temperature/humidity data logger (see Chapter 6) and used that location as plot center. This process resulted in the random selection of a point that was still within the male's territory. These points were marked in the field with flagging, which remained in place over the 2008–2009 winter.

In 2009, we identified the territory center for each resident male as described above. If an existing sampling point was within 20 m of the territory center identified in 2009, we assigned that existing point to the current territory. If there was no existing point within 20 m of the territory center, we located a new sampling point as described above. Sampling points that were identified in 2008 but were not within 20 m of a territory center in 2009 were resampled in 2009. Data from these points are not included in the

2009 data presented below but may be used in future analyses to identify any changes in vegetation that may lead to territory abandonment.

At each plot, we laid out four 5-m-long ropes from plot center, one in each of the four cardinal directions. Each rope was marked at 1 m and 5 m from the center of the plot. At plot center and at 1 m and 5 m from the center of the plot in each cardinal direction, we measured vertical foliage density using a 7.5-m-tall survey rod. Working our way up the rod, we recorded the presence of vegetation, by species, within a 10-cm radius of the rod in 0.1-m intervals (presence of the species within the 0.1-m interval equaled one "hit" on the rod), and summed all hits in 1-m intervals. Presence of dead vegetation (snags) was recorded in the same manner, but not identified to species. If canopy vegetation continued above 8.0 m, we estimated the number of hits as zero, greater than five, or less than five hits per 1-m interval until the canopy vegetation stopped (modified from Rotenberry 1985).

We measured total canopy closure using a Model-A spherical densiometer at 1 m north and south of the center of each plot and averaged these measurements to obtain a single canopy closure value for each plot. We measured average canopy height within each plot by selecting a representative tree and using a survey rod or a clinometer and measuring tape to measure the height of the selected tree. We estimated percent woody ground cover, alive and dead, within 0.5 m of the ground using a Daubenmire-type frame with the lower edge of the frame centered at 1 m north, south, east, and west of plot center. These percentages were averaged to obtain a single measure of percent woody ground cover for each plot.

We tallied the number of live stems for each species within 5 m of the center of the plot. Stems were tallied if they were at least 1.4-m tall and >2.5 cm in diameter at 10 cm above the ground. Stems were tallied by the following diameter at breast height (dbh) categories: <1 cm, 1–2.5 cm, 2.6–5.5 cm, 5.6–8 cm, 8.1–10.5 cm, and 10.5–15 cm. Any stems >15 cm dbh were measured and the exact dbh was recorded. Dead stems were also tallied in these categories, but not identified to species. In 2009, we marked each stem with a piece of chalk after it was tallied to facilitate accurate stem counts.

During vegetation sampling in 2003–2007, if a stem branched above 10 cm but below 1.4 m above the ground, only the largest stem was tallied. In habitats (e.g., tamarisk) where stems frequently branch in this height interval, this method of counting stems may underestimate the density of stems that form an important part of the habitat structure. Therefore, in 2008 and 2009 we tallied stems as we had in previous years and then for each stem that branched between 10 cm and 1.4 m from the ground, we tallied the number of additional stems that were at least 2.5 cm in diameter at 10 cm above the point where it branched from the main stem.

Additional information recorded at each plot included the date when the measurements were taken, observer initials, and UTM coordinates for each plot center.

Nests in Formerly Occupied Areas

The same measurements that were completed at occupied territories were also taken at old nest sites. We used the UTM coordinates of the nest, nest tree species, nest height, and nest flags that remained in the field to locate the old nests. Vegetation plots were centered on the nest location. Each old nest was at least 50 m from any nest or territory center that was active in 2009.

Data Analyses

We used high-resolution aerial photography and field knowledge of each study area to delineate clusters of territories that occur within habitat patches of similar floristics and canopy height. Vegetation characteristics were then summarized for each habitat type. The habitat types delineated in this report do not follow the classification system used by Anderson and Ohmart (1984) and will be related to Anderson and Ohmart (1984) classifications in a future report. We used SPSS® Version 16.0 (SPSS Inc.) software for statistical analyses.

Stem counts were grouped into the following size categories for analysis: <2.5 cm dbh, 2.5–8 cm dbh, and >8 cm dbh. For each size category, stem counts are reported separately for live and dead stems; the sum of these is the equivalent of the stem counts per size category that were reported in the 2003–2007 summary report (McLeod et al. 2008). Vertical foliage density measurements above 8.0 m that were recorded as < or >5 hits per meter were converted to 2.5 and 7.5 hits, respectively, to allow analyses of these data as continuous rather than categorical. Vertical foliage density was calculated for each meter interval as the mean of the number of hits recorded within the interval at the nine locations in the plot. In 2003–2007, we had measured vertical foliage density only at plot center and 1 m from plot center in each cardinal direction, and foliage density measures per meter interval were presented as the sum of the hits recorded at the five locations in the plot. Thus, vertical foliage data presented in reports from 2003 to 2007 should be divided by 5 to be comparable to data presented here. In the five-year summary report (McLeod et al. 2008), vertical foliage data were grouped into three categories of above, at, and below the nest. We used average nest height as measured in 2003–2009 in each vegetation type to demarcate vertical foliage categories in 2009. As with stem counts, vertical foliage data are reported separately for live and dead vegetation.

Percent native vegetation was calculated as the average of the percent basal area that was native and the percent native vertical foliage hits. For data collected in 2003–2007 (reported in McLeod et al. 2008), we did not use vertical foliage data to calculate percent native because all vertical foliage data were collected within 1 m of plot center and represented only a small portion of the plot. We included vertical foliage data in the percent native calculations in 2009 to account for the influence of stems that were too small to be tallied or were rooted outside the 5-m-radius circle but overhung the plot.

We used non-parametric Wilcoxon signed rank tests for related samples to compare vegetation measurements collected at old nests to the measurements collected during the year the nest was active. We chose non-parametric tests because several parameters had non-normal distributions. Vertical foliage data used in these comparisons were restricted to data collected within 1 m of plot center so as to be directly comparable to data collected prior to 2008. A statistical significance level of $P \leq 0.05$ was chosen to reject null hypotheses.

RESULTS

Currently Occupied Territories

We measured vegetation at 56 occupied territories and 15 territories that were occupied in 2008 but not in 2009 at Littlefield, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams. We delineated the following habitat types: 1) coyote willow, 2) tamarisk/coyote willow mix, 3) Goodding willow, 4) Goodding willow with tamarisk understory, 5) tamarisk with scattered Goodding willow, 6) tamarisk, and 7) cottonwood/mesquite mix. Coyote willow and tamarisk/coyote willow mix occurred at Mesquite, with coyote willow dominating the eastern half of the site while tamarisk and

coyote willow were mixed in the western half of the site. One location at Topock also consisted of a mix of tamarisk and coyote willow, but exceedingly dense vegetation at this location prevented us from collecting stem count data. Goodding willow occurred in the southern portion of Muddy River, in a small stand readily discernible on high-resolution aerial photographs, and at Littlefield. Goodding willow with tamarisk understory occurred at Bill Williams. Tamarisk with scattered, emergent Goodding willow occurred both at Mormon Mesa and Topock; these two study areas were summarized separately because several variables, including canopy height and canopy closure, differed between the two areas. Tamarisk habitats lacking emergent willows occurred at Mesquite, Muddy River, and Topock, while cottonwood with mesquite occurred at the Beal Lake restoration site at Topock. Average nest height recorded in 2003–2009 and used to assign vertical foliage strata for each vegetation category were 2.1, 2.4, 2.8, 4.2, 2.5, 3.5, and 3.7 m for coyote willow, tamarisk/coyote willow mix, Goodding willow, Goodding willow with tamarisk understory, tamarisk with scattered Goodding willow at Mormon Mesa, tamarisk with scattered Goodding willow at Topock, and tamarisk, respectively. No nests were known from cottonwood/mesquite habitat, so the overall mean nest height of 2.9 m was used to assign vertical foliage categories for that vegetation type.

Vegetation characteristics of each habitat type are summarized in Table 5.1. Habitat types varied widely in many characteristics, and plots within each habitat type also showed a wide range in most habitat variables.

The proportion of stems omitted from stem counts by counting only the largest stem of a cluster that branched between 10 cm and 1.4 m above the ground varied both by size and species of the main stem (Table 5.2). Tamarisk had the highest proportion of omitted stems, and larger stems had more branches that were omitted.

Vertical foliage profiles for each habitat type are shown in Figures 5.1–5.8. Average nest height in each habitat type, as recorded in 2003–2009, is also shown on each graph. No nests were recorded in cottonwood/mesquite habitat, so average nest height across all habitat types is shown on this graph. In all habitat types, the proportion of dead vegetation in the vertical profile was highest immediately above the ground and declined with increasing height. In most habitat types, the densest live foliage occurred between 2 and 4 m above the ground and was near average nest height.

Nests in Formerly Occupied Areas

We gathered vegetation data at 26 old nests at Mormon Mesa and Topock. We were able to locate the exact nest fork in 17 cases and located the nest tree but were unsure of the correct fork in 5 additional cases. In four cases we located the nest vicinity (within 5 m of the nest location) but were unable to verify that we had located the exact nest tree.

Vegetation at nest sites differed between occupied and unoccupied periods in more than one variable at each study area; however, the characteristics that differed were not consistent among sites (Table 5.3). At Mormon Mesa, nest sites had shorter canopy, less canopy closure, more woody ground cover, fewer dead stems 2.5–8 cm dbh, more dead stems >8 cm dbh, and less dead foliage above nest height when they were active compared to when the area was abandoned. At Topock, nest sites had shorter canopy, less woody ground cover, fewer live stems >8 cm dbh, and fewer dead stems 2.5–8 cm dbh when they were occupied. When both study areas were combined (Table 5.4), nest sites had shorter canopy height, fewer live stems <2.5 cm dbh, more live stems >8 cm dbh, and fewer dead stems 2.5–8 cm dbh when they were active versus when the territory was abandoned. The only variables that differed consistently across the two study areas were canopy height and number of dead stems 2.5–8 cm dbh, both of which were greater in 2009 than in the year the nest was active.

[1] Arrows indicate the direction of change of the variable between occupied and unoccupied periods for each study area (MOME = Mormon Mesa, TOPO = Topock Marsh, while color indicates the statistical significance of the change as follows: red is P <0.05, green is 0.05< P <0.10, black is P >0.10.

DISCUSSION

Currently Occupied Territories

The purpose of vegetation measurements of occupied habitat is to provide quantitative guidelines for restoration efforts. Coyote willow and Goodding willow are the two habitat types that are known to support breeding flycatchers and are most likely to be replicated in restoration areas. Mesquite West contains the only extensive stand of coyote willow known to be occupied by territorial willow flycatchers along the lower Colorado River and tributaries in any year since 2003. Occupied coyote willow habitat at Mesquite encompasses approximately 3 ha in the eastern and central portions of Mesquite West and is surrounded by cattail marsh and mixed coyote willow and tamarisk. Occupied even-age Goodding

willow habitat occurred in 2009 on less than 1 ha on the southern end of the Overton WMA site at Muddy River and at Littlefield on Beaver Dam Wash.

Sample sizes for the coyote willow and Goodding willow habitat types in 2009 are small (eight and five, respectively) and likely do not provide an accurate representation of the range and variance in vegetation characteristics in each habitat type. In future reports, data from 2009 will be combined with data collected within active territories between 2003 and 2008 to provide a more comprehensive description of each habitat type.

The cottonwood-mesquite habitat type occurred at the Beal Lake restoration area at Topock. Although flycatchers were detected on multiple occasions at Beal Lake, they responded to broadcast but did not engage in the lengthy, unsolicited song typical of territorial male flycatchers. The flycatchers detected at Beal Lake could not be resighted to determine band combinations, and it is unknown whether a given individual remained at Beal Lake or whether different individuals were detected on different occasions. Beal Lake is a mosaic of vegetation types and densities (see description in Chapter 2). The vegetation plot measured at Beal Lake had less canopy closure and far fewer stems than was typical for flycatcher territories in other habitat types, but more extensive sampling would be required to ascertain whether the plot is representative of the site. Because of the uncertainty of whether the site was truly occupied by resident flycatchers and the dissimilarities between the vegetation characteristics measured at Beal Lake and at other flycatcher territories, the vegetation characteristics reported here for cottonwood-mesquite habitat should not be used as a model for flycatcher habitat.

Although other vegetation types occupied by willow flycatchers are not likely to be created in restoration areas, descriptive data are provided for these habitats to assist in the evaluation of areas to determine their suitability as flycatcher breeding habitat. Data from these other vegetation types may also be useful in illustrating structural similarities between occupied areas in different habitat types. Small sample sizes preclude meaningful comparisons of the 2009 data across habitat types.

Nests in Formerly Occupied Areas

Old nests at Mormon Mesa occurred in Virgin River #2, where we first documented nesting flycatchers in 2005. We had not surveyed the area in 2003–2004, but old flagging suggested that the area could have been occupied by flycatchers in years prior to 2003. The site was occupied by breeding flycatchers in each year from 2005 to 2008. The breeding area contained surface water and saturated soil in 2005 and 2006 but was dry in 2007–2009. No dramatic changes in vegetation were apparent from the site descriptions between 2005 and 2009, but one observer thought a much larger proportion of the tamarisk understory appeared dead in 2009 than in 2006, when she had last visited the site (M.A. McLeod pers. obs.). This observation was supported by there being more dead stems 2.5–8 cm dbh and more dead vegetation above nest height in 2009 than in the year the nest was active. However, the vegetation data also showed there were fewer dead stems >8 cm dbh and greater canopy closure in 2009, which appears to contradict there being more dead foliage.

The majority of old nests at Topock occurred in the adjacent sites of 800M and In Between, with one additional nest in Pipes #3. Paired flycatchers were present at 800M and In Between in 2003–2007, though the number of pairs at the two sites declined from 10 in 2004 to 2 in 2007, with no pairs detected in 2008 or 2009. Pipes #3 was occupied by resident flycatchers in 2004–2006 and again in 2009, though breeding was detected only in 2004. As at Mormon Mesa, no changes in vegetation were apparent over the years from the site descriptions, but one observer thought the tamarisk at In Between and 800M had a higher proportion of dead stems and less canopy closure in 2009 than in years when there were active nests in the area (T.J. Koronkiewicz pers. obs.). This observation was supported by there being more dead stems 2.5–8 cm dbh and a trend toward decreased canopy closure in 2009 than in the year the nest

was active. However, vegetation data also showed an increase in the number of live stems <2.5 cm and >8 cm dbh.

Although the methods for collecting the vegetation data used in these analyses were unchanged among years, observer variation could influence between-year differences in stem counts, vertical foliage counts, and canopy closure. To address observer variation in stem and vertical foliage counts, we calculated the proportion of live stems and live hits in each category and then compared the proportions between the occupied and unoccupied periods. As long as each observer counts live vs. dead stems and, similarly, live vs. dead hits in a consistent manner, this technique accounts for any observer differences in the absolute counts. Results of this analysis showed that the proportion of live stems 2.5–8 cm dbh decreased at both Mormon Mesa (0.57 to 0.44, P = 0.039) and Topock (0.72 to 0.50, P = 0.007) and when both study areas were combined (0.64 to 0.47, P = 0.001) between the occupied year and 2009. A decrease in the proportion of live, medium-sized stems could reduce the suitability of the area for flycatchers. The proportion of live stems >8 cm dbh increased at Topock (0.84 to 0.96, P = 0.025), but this variable did not differ between the occupied year and 2009 at Mormon Mesa or when both study areas were combined. Spatial rather than temporal comparisons of occupied and unoccupied areas in 2003–2007 showed that the number of stems 2.5–8 cm dbh was an important factor distinguishing occupied from unoccupied areas, but live and dead stems were not analyzed separately (McLeod et al. 2008). Reanalysis of the 2003–2007 data incorporating the proportion of live vs. dead vegetation may yield further insight into the vegetation characteristics that contribute to flycatcher occupancy.

Canopy height increased at both Mormon Mesa and Topock between occupied and unoccupied periods, likely as the result of vegetation maturing over the years. This increase in canopy height probably did not contribute to abandonment of the area; McLeod et al. (2008) reported that flycatchers typically occupied areas that had greater canopy height than unoccupied areas. Canopy closure increased at Mormon Mesa between occupied and unoccupied periods but showed a decreasing trend at Topock. Given that flycatchers typically nest in areas with very high canopy closure (McLeod et al. 2008) it is unlikely that an increase in canopy closure would contribute to site abandonment. The apparent changes in canopy closure at both Mormon Mesa and Topock were small (<6%) and may be the result of observer variation.

Chapter 6

MICROCLIMATE

INTRODUCTION

Our objective for microclimate sampling is to provide a quantitative summary of microclimate conditions within occupied territories in various vegetation types. These descriptive summaries will provide guidance for managers working to restore and create riparian habitat to meet the obligations of the LCR MSCP and will provide a means to evaluate habitats to determine if the microclimate resembles that in occupied flycatcher territories. The Pahranagat study area was excluded from the characterization of occupied territories because the study area is approximately 650 m higher in elevation and experiences a cooler climate than the LCR MSCP study area.

In addition, we investigated whether changes in microclimate characteristics might have contributed to the abandonment of some areas by flycatchers. We identified several areas that had been occupied by nesting flycatchers in at least one previous year from 2003 to 2007 but were unoccupied in 2009, and we relocated old nest sites at which we had collected microclimate information in the year the nest was active. We resampled the microclimate at these nests to see whether microclimate characteristics had changed. Comparison of microclimate data collected when a nest site was active versus when the area was abandoned may elucidate how changes in microclimate through time may influence flycatcher occupancy. These results will provide additional quantitative information on the characteristics of microclimate within flycatcher nesting territories.

METHODS

Currently Occupied Territories

Temperature and Relative Humidity (T/RH) Measurements

Measurements of temperature and relative humidity (T/RH) were recorded automatically every 15 minutes using a HOBO H8 Pro (Onset Computer Corporation, Pocasset, MA) that combines a thermometer (degrees Celsius), relative humidity monitor, and digital data logger. We camouflaged all HOBO units by placing them in an inverted small, plastic container coated with spray adhesive and local vegetation. The opening at the bottom was covered with shadecloth, allowing free air circulation around the unit.

In 2008, we collected microclimate measurements at one location for each resident male flycatcher we identified, regardless of the length of time the male was resident and whether or not he obtained a mate. One HOBO unit was placed within each active flycatcher territory. We estimated the center of the male's territory (see Chapter 5) and then determined the location of the HOBO unit by means of the following instructions and the use of random number sequences:

(1) The compass direction to walk from the territory center, given in degrees from north, was determined from a random number sequence.

(2) The distance (between 0 and 20 m) to walk in the designated direction was determined from a random number sequence. Once that distance was traveled, the closest woody tree or shrub was selected for data logger placement.

(3) The HOBO unit was placed at a randomly selected height within the range of flycatcher nest heights documented at that study area in 2003–2007 (McLeod et al. 2008). The distribution of random numbers followed the distribution of nest heights. If the chosen tree or shrub was of insufficient height to accept the height from the random number sequence, then field personnel placed the HOBO unit at the first height in the sequence that was less than the height of the tree or shrub. If no nests had been previously recorded at that study area, field personnel used the height sequences from the nearest study area with known nests.

(4) The distance (0–2 m) at which the HOBO was placed from the bole of the tree or center of the shrub was determined from a random number sequence. If the tree or shrub was of insufficient radius to accept the distance from the random number sequence, then field personnel placed the unit at the first number in the sequence that was less than the radius of the tree or shrub.

(5) The compass direction, given in degrees from north, at which the unit was placed from the bole of the tree or center of the shrub was determined from a random number sequence. If there was no branch in this compass direction that would support the data logger at the height and distance specified in (3) and (4), field personnel proceeded clockwise around the tree or shrub until a suitable branch was located.

If, as presented in (3) and (4), a number from a subsequent random number sequence (sequence meaning a row in the random number table) was used because the number in the initial sequence was too high, then both sequences were considered used and no longer available for future use. If these directions took field personnel outside of the riparian zone or to a site without trees or shrubs, they returned to the territory center and used the next sequence of random numbers.

HOBO loggers remained in the field over the 2008–2009 winter at these locations and were downloaded and redeployed in the same location in early May 2009. During the breeding season of 2009, we identified the territory center for each resident male. If an existing sampling point was within 20 m of the territory center identified in 2009, we assigned that existing point to the current territory. If there was no existing point within 20 m of the territory center, we located a new sampling point as described above. Sampling points that were identified in 2008 but were not within 20 m of a territory center in 2009 were resampled in 2009. Data from these points are not included in the 2009 data presented below but may be used in future analyses to identify any changes in vegetation that may lead to territory abandonment. All HOBO units were removed from the field at the end of the breeding season because of the large number of data logger losses experienced over the 2008–2009 winter.

Soil Moisture (SM) Measurements

A ThetaProbe ML2x coupled to an HH2 Moisture Meter Readout (Macaulay Land Use Research Institute, Aberdeen, UK, and Delta-T Devices, Cambridge, UK, respectively) was used to gather soil moisture (SM) data. The SM readings (nine per site) were recorded directly beneath the HOBO logger (plot center) and at 1.0 and 2.0 m from plot center in each cardinal direction. Soil moisture readings were collected when the HOBO logger was downloaded (for loggers in place since 2008) or deployed (for locations new in 2009) and at two-week intervals throughout the breeding season until the HOBO logger was removed at the end of the season. Soil moisture was recorded both as voltage (mV) and as volumetric water content (%).[1] Soil type on the HH2 was set to mineral soil. For any SM measurement point that was underwater, we recorded the depth of standing water and assigned a value of 994 mV, which is equivalent to 50% volumetric water content, or fully saturated soil. All mV values greater than

[1] The soil moisture logger measures the dielectric constant of moist soil via a direct current voltage, which is converted to volumetric soil moisture with conversion tables. For very high (above ~1000 mV) or low (below ~90 mV) voltage readings, the HH2 reports volumetric soil moisture as "above" or "below" the table, respectively. To eliminate these qualitative readings, we recorded both mV and volumetric soil moisture.

994 were also reassigned as 994 mV, because this reading represents fully saturated soil and because the mV to percent relationship becomes excessively nonlinear for mV readings above this point. Each time we collected soil moisture data, we also recorded the distance to the nearest standing water or saturated soil and recorded the approximate percentage, as estimated in the field, of the site within 20 and 50 m of the data logger that contained inundated or saturated soil.

A soil sample was collected from beneath each HOBO location that was new in 2009. Samples were approximately the size of a medium apple, collected from the surface down to and including a depth of 5 cm, and placed in a heavy zip-lock plastic bag labeled with the site designation. These samples will contribute to an ongoing analysis of soil texture, which strongly influences capillary action and therefore overall SM (Sumner 2000). Results of the soil texture analysis will be presented in the 2012 summary report.

Statistical Analyses

Soil moisture data were entered into a database as they were collected during the field season. We downloaded data from the HOBO data loggers into databases at the end of the field season. We merged all data to create one dataset for further analysis. We summarized the following variables for each HOBO location:

- Mean soil moisture from plot center to 2.0 m from plot center
- Distance to nearest standing water or saturated soil
- % of the site within 20 m that was inundated or saturated
- % of the site within 50 m that was inundated or saturated
- Maximum diurnal temperature
- Minimum nocturnal temperature
- Daily temperature range (diurnal maximum minus nocturnal minimum)
- Mean diurnal vapor pressure[2]
- Mean nocturnal vapor pressure

Soil moisture variables were summarized per visit, and temperature/humidity variables were summarized on a daily basis. We determined diurnal and nocturnal periods by using the actual daily sunrise and sunset times reported for the region by the National Weather Service (2009). We selected the above measures of temperature and humidity for analysis because they were the most highly correlated with other variables or were the most useful in distinguishing use areas from non-use locations (McLeod et al. 2008). Territories were grouped according to vegetation type (see Chapter 5), and microclimate variables were averaged for each vegetation type over the following two-week periods to show how microclimate conditions changed throughout the breeding season: 16–31 May, 1–15 June, 15–30 June, 1–15 July, 16–31 July, and 1–15 August.

Analyses were conducted using SAS® v.9.1.3 (SAS Institute 2003) and Stata® v.9.2 (StataCorp 2006). Data are presented as mean (standard error) unless otherwise noted.

[2] Vapor pressure, unlike relative humidity, is not influenced by ambient temperature, and may be a more biologically meaningful measure of water content of the air (e.g., the relative vapor pressure inside and outside an egg determines whether the egg loses moisture). We calculated vapor pressure from the absolute humidity and temperature recorded by the HOBOs.

Nests in Formerly Occupied Areas

We used the UTM coordinates of the nest, nest tree species, nest height, and nest flags that remained in the field to locate old nests. During the year when each nest was active, microclimate data were collected for a two-week period immediately following the nest being vacated. In 2009, we hung a HOBO logger at the old nest location on or before the date on which the HOBO was deployed in the year the nest was active and removed the logger on or after the date the logger was removed in the year the nest was active. Soil moisture measurements were taken at the beginning and the end of the two-week period during which the HOBO was deployed in the year the nest was active.

Statistical Analyses

We truncated the temperature and humidity data collected in 2009 to match the two-week period during which data were collected in the year the nest was active. We summarized the following variables for each HOBO location:

- Mean soil moisture from plot center to 2.0 m from plot center
- Maximum diurnal temperature
- Minimum nocturnal temperature
- Daily temperature range (diurnal maximum minus nocturnal minimum)
- Mean diurnal vapor pressure[3]
- Mean nocturnal vapor pressure

We used paired t-tests to compare measures of microclimate at old nests to the measurements collected during the year the nest was active. P-values were similar to those obtained when a non-parametric test (Wilcoxon signed rank sum) was used to compare matched sites. Analyses were conducted using SAS® v.9.1.3 (SAS Institute 2003) and Stata® v.9.2 (StataCorp 2006). Missing data were excluded test-wise. Data are presented as mean (standard error) unless otherwise noted.

To address whether any observed changes in microclimate between occupied and unoccupied periods could be the result of overall changes in regional climate, we obtained weather station data from the National Climate Data Center (www.ncdc.noaa.gov/oa/ncdc.html) for Overton, Nevada (Station ID #265846) and Needles, California (Station ID #46118) for 2003–2009. Maximum and minimum daily temperature data were available for both weather stations, and dew point data were available for Needles. We used one-way ANOVA to test whether temperature and dew point variables differed between years for the June–August period. We used SPSS® Version 16.0 (SPSS Inc.) software for statistical analyses.

[3] Vapor pressure, unlike relative humidity, is not influenced by ambient temperature, and may be a more biologically meaningful measure of water content of the air (e.g., the relative vapor pressure inside and outside an egg determines whether the egg loses moisture). We calculated vapor pressure from the absolute humidity and temperature recorded by the HOBOs.

RESULTS

Currently Occupied Territories

We collected microclimate data at 56 active territories and 15 territories that were occupied in 2008 but not in 2009. HOBO loggers failed to collect data at four active territories and one location that was occupied in 2008 but not 2009. Four additional loggers at active territories and one logger at an unoccupied location had bad humidity sensors. Microclimate variables are summarized by two-week periods for each vegetation type in Tables 6.1–6.8. These same variables are plotted in Figures 6.1–6.9 to facilitate comparisons between vegetation types.

All vegetation types except cottonwood/mesquite exhibited moist soil conditions at some point during the breeding season. Goodding willow and tamarisk with scattered willow at Mormon Mesa maintained the overall wettest conditions through the season, with high soil moisture readings and a high percentage of the surrounding area being inundated. Goodding willow with tamarisk understory also had high soil moisture content throughout the season, but distance to surface water increased dramatically as the summer progressed. Soil conditions showed a general drying trend in several habitat types, with the inundated percentage of the surrounding area declining through the season in Goodding willow, Goodding willow with tamarisk understory, tamarisk, and tamarisk with scattered Goodding willow at Topock. Coyote willow and tamarisk with coyote willow both had relatively dry soils, particularly at the beginning of the breeding season.

Mean daily maximum temperatures spanned a range of <10°C among habitat types. Daily minimum temperatures showed a smaller range of <5°C. Cottonwood/mesquite, coyote willow, and tamarisk with coyote willow showed the largest daily temperature ranges throughout the season, while Goodding willow with tamarisk understory and tamarisk with scattered willow at Topock had the most moderate temperature ranges.

Vapor pressure increased through the end of July for all habitat types. Vapor pressure was highest in Goodding willow with tamarisk understory and in tamarisk with scattered willow at Topock. Vapor pressure at the beginning of the season was lowest in coyote willow and tamarisk with coyote willow. In July, these two habitat types along with Goodding willow and tamarisk with scattered willow at Mormon Mesa had lower vapor pressure than the other habitat types.

Nests in Formerly Occupied Areas

We located 26 old nests at Mormon Mesa and Topock Marsh. We were able to locate the exact nest fork in 17 cases and located the nest tree but were unsure of the correct fork in 5 additional cases. In four cases we located the nest vicinity (within 5 m of the nest location) but were unable to verify that we had located the exact nest tree. Three of the 26 HOBO data loggers failed to collect data, while two loggers collected temperature but no humidity data. Soil moisture data from the occupied period were unavailable for the two nests that were active in 2003.

Microclimate at old nests sites differed between occupied and unoccupied periods in at least one variable at both Mormon Mesa (Table 6.9) and Topock Marsh (Table 6.10). At Mormon Mesa, nest sites had higher diurnal and nocturnal vapor pressure when they were occupied versus when they were abandoned. At Topock Marsh, nest sites had higher nocturnal vapor pressure when the nest was occupied. When data from both sites were pooled, mean diurnal and nocturnal vapor pressure were lower in 2009 versus when the nest was occupied (Table 6.11). The only variables that showed a unidirectional change across study areas were soil moisture and nocturnal vapor pressure, both of which were lower in 2009 versus when the nest was occupied.

Mean daily maximum temperature recorded at the Overton weather station in June–August 2009 (105.3 °F) was lower ($F_{6,630} = 2.7$, $P = 0.014$) than in the same period in 2003 or 2007 (both 108.5 °F). Mean daily minimum temperature at Overton was higher ($F_{6,630} = 8.9$, $P < 0.001$) in 2009 (72.5 °F) than in 2005 (69.3 °F) or 2007 (68.8 °F). At the Needles weather station, mean maximum daily temperature was lower ($F_{6,637} = 6.3$, $P < 0.001$) in June–August 2009 (106.9 °F) than during the same period in 2006 (111.0 °F). Mean minimum daily temperature in 2009 (81.4 °F) was also lower than in 2006 (85.5 °F) ($F_{6,637} = 5.9$, $P < 0.001$). Average dew point at Needles was lower ($F_{6,637} = 13.9$, $P < 0.001$) in 2009 (38.8 °F) than in 2003 (55.7 °F), 2004 (48.3 °F), or 2006 (45.6 °F).

[1] Arrows indicate the direction of change of the variable between occupied and unoccupied periods for each study area (MOME = Mormon Mesa and TOPO = Topock Marsh), while color indicated the statistical significance of the change as follows: red is P <0.05, green is 0.05<P<0.10, black is P >0.10.

DISCUSSION

Currently Occupied Territories

The hydrological conditions recorded in occupied territories in 2009 show that Goodding willow, tamarisk, tamarisk with scattered willow at Topock, and Goodding willow with tamarisk understory habitat types contained the wettest soils at the beginning of the breeding season, with the distance to surface water being less than 30 m and up to 70% of the surrounding area within 50 m containing saturated or inundated soil. Soils became progressively drier throughout the season in all these habitat types, though the speed and extent to which the soils dried out varied among habitat types.

The coyote willow and tamarisk with coyote willow habitat types, both of which are present at Mesquite West, showed a notable departure from the wet conditions observed there in previous years. The Mesquite West site did not receive any surface water until June (see Chapter 2), and the hydrological data show the low soil moisture, low percentage of the area inundated, and high distance to surface water observed at the site in 2009. Despite the dry soil conditions, both habitat types were occupied by breeding flycatchers, though occupancy likely reflects the high site fidelity of adult flycatchers (see Chapter 3) rather than the suitability of the hydrologic conditions for creating and maintaining flycatcher habitat.

The lowest soil moisture values were recorded in the cottonwood/mesquite habitat type at the Beal Lake restoration area. This area is flood irrigated but contains very sandy soil and thus dries quickly. Although flycatchers were detected on multiple occasions at Beal Lake, they responded to broadcast but did not engage in the lengthy, unsolicited song typical of territorial male flycatchers. No flycatcher breeding activity has been detected in this habitat type along the LCR, and this habitat type should not be used as a model for flycatcher habitat

Tamarisk with scattered Goodding willow at Mormon Mesa was the only vegetation type that was influenced by an undammed river. Unlike in most previous years, the Virgin River at Mormon Mesa did not go completely subsurface at any time during the breeding season, and occupied flycatcher habitat at Mormon Mesa did not lose its saturated and inundated soils in 2009 as it had in previous years.

Temperature and humidity varied across habitat types. As in 2008, Goodding willow with tamarisk understory was the most humid, followed by tamarisk with scattered willow at Topock. These two habitat types were also the most thermally stable. In previous years, tamarisk with scattered willow at Mormon Mesa had the highest temperature, largest daily temperature range, and lowest humidity (McLeod et al. 2008, McLeod and Koronkiewicz 2009), but in 2009, coyote willow and tamarisk with coyote willow had daily temperature ranges higher than and humidity comparable to territories at Mormon Mesa. The less humid and less thermally moderate conditions in coyote willow and tamarisk with coyote willow habitat types may be related to the lack of surface water in Mesquite West.

Nests in Formerly Occupied Territories

Willow flycatchers along the lower Colorado River and tributaries selected nest sites that were cooler, wetter, and more thermally moderate than unused sites in the adjacent landscape (McLeod et al. 2008), and we anticipated seeing similar differences when we examined temporal, rather than spatial, variation in habitat use. The only statistically significant differences we observed (lower mean diurnal and nocturnal vapor pressure at Mormon Mesa and lower nocturnal vapor pressure at Topock Marsh in 2009 versus when the nest was active) were consistent with these expectations. However, the mean dew point at the Needles weather station in June–August 2009 was lower than in the corresponding months in 2003, 2004,

or 2006, suggesting that regional climate could have accounted for the observed differences in vapor pressure at nest sites in Topock Marsh. Humidity data were not available for the Overton weather station, but a qualitative comparison of vapor pressure observed at occupied territories at Mormon Mesa in 2009 versus that observed in 2003–2007 (McLeod et al. 2008) suggests that overall humidity was lower in 2009. Thus, the differences in microclimate we observed between 2009 and the year the nest was occupied at both Topock and Mormon Mesa are likely the result of interannual climatic differences and not the result of localized changes at the nest sites. We found some evidence of an increase in the proportion of dead stems at old nests at both Topock and Mormon Mesa (see Chapter 5), but otherwise found no evidence of dramatic changes in vegetation at formerly occupied territories that might result in changes in temperature or humidity. It is possible that subtle changes in vegetation (see Chapter 5) were sufficient to reduce suitability of the sites for flycatchers. It is also possible that changes in occupancy patterns at Topock Marsh may be influenced by an overall decrease, since 2004, in the number of nesting pairs (see Chapter 4).

Soil moisture values did not differ significantly between unoccupied and occupied periods at either study area, and a post-hoc analysis comparing the distance to surface water during occupied vs. unoccupied periods showed no statistical difference at Mormon Mesa (data on distance to water at Topock were too sparse to allow analysis). Surface water conditions at the Virgin River #2 site, where the formerly occupied territories at Mormon Mesa were located, nonetheless differed notably over time, with the occupied territories containing surface water throughout the season in 2005 and at the beginning of the season in 2006 but not in subsequent years. The affinity of willow flycatchers with surface water is well documented in the literature, and the presence of surface water likely affects flycatcher settlement at the beginning of the breeding season. Adult flycatchers also demonstrate high site fidelity, and will return to previously used breeding areas even if conditions are no longer optimal. Thus, it is possible that Virgin River #2 has not represented optimal flycatcher habitat for multiple years, but site fidelity maintained the presence of breeding flycatchers through 2008.

Chapter 7

HABITAT MONITORING: PARKER TO IMPERIAL DAMS

INTRODUCTION

Southwestern Willow Flycatcher nests and breeding territories are typically located near rivers, streams, and open water (Sogge and Marshall 2000) or over wet soil (Flett and Sanders 1987, Harris et al. 1987, Harris 1991). Nest substrate plants are often rooted in or overhang standing water. Although the association between breeding flycatchers and open water or wet soil is widely recognized by managers and scientists alike, the exact nature of the association is poorly quantified. Water may be a direct environmental cue for flycatcher nesting behavior or it may be the ultimate cause of proximate factors such as vegetation composition and structure, prey base, and microclimate.

Anthropogenic or natural modifications to surface water resources (i.e., fluvial hydrology and geomorphology) can modify existing and potential flycatcher breeding habitat and therefore have the potential to modify flycatcher abundance, distribution, and nesting success (Graf et al. 2002). For example, nine flycatcher territories at San Marcial on the middle Rio Grande in New Mexico exhibited a near absence of nesting attempts in 1996 when a combination of drought, upstream dam operations, and upstream withdrawals for irrigation removed all surface water (Johnson et al. 1999). This was in contrast to previous (1994, 1995) and subsequent (1997) years when active nests were documented at the site, with the river flowing in those years. A nearby control site that contained water exhibited multiple nesting attempts during all four years, leading Johnson et al. (1999) to suggest that the presence of water was a fundamental requirement for nesting. A similar pattern was observed along the Gila River in Arizona when decreased streamflow from 2002 to 2004 coincided with the number of flycatcher territories declining by nearly half each year (Munzer et al. 2005). Since 2004, flows within the Gila River have been greater and more consistent, and correspond with a continuing increase in flycatcher territories (14 to 97) from 2004 to 2009 (Graber and Koronkiewicz 2009b).

Flow characteristics of the lower Colorado River have been modified by numerous dams and irrigation withdrawals (Rosenberg et al. 1991). The river reach between Parker Dam and Imperial Dam is regulated by releases from Parker Dam, which has been in operation since 1939. Existing riparian habitat in the Parker to Imperial reach has likely adjusted to historical water release patterns from Parker Dam and appears to be in a stable or declining condition (LCR MSCP 2004). Implementation of the Secretarial Implementation Agreements/California 4.4 Plan (hereafter SIAs) by Reclamation would change the point of diversion for up to 400,000 acre-feet of California apportionment water for up to 75 years (USFWS 2001). The point of diversion, previously located below Parker Dam at Imperial Dam, would change to a point above Parker Dam, resulting in lower water levels in the river between Parker and Imperial. The change in point of diversion was scheduled to begin in 2002.

River flow changes related to the change in point of diversion have the potential to further modify riparian habitats below Parker Dam, habitats that are presently considered potentially suitable for willow flycatcher (USFWS 2001:47). Reclamation (2000) estimated that implementation of the SIAs will cause a drop in floodplain groundwater levels of 1.55 feet (0.47 m) or less. As a result, 372 acres (151 ha) of occupied[1] Southwestern Willow Flycatcher habitat could lose their moist soils. This loss could influence plant species composition (loss of cottonwood and willow) and structure (loss of vegetation volume) over an undetermined length of time. In addition, Reclamation estimated that 5,404 acres (2,187 ha) of

[1] As per the USFWS, occupied Southwestern Willow Flycatcher habitat is defined as patches of vegetation that are similar to and contiguous with areas where willow flycatchers were detected after 15 June in any year since surveys began in 1996.

potential flycatcher habitat could be influenced by the drop in groundwater level. These changes may affect the distribution, abundance, occupancy, and prey base of Southwestern Willow Flycatchers in the Parker to Imperial reach.

In 2004, Reclamation completed a pilot year of habitat monitoring by deploying temperature/ humidity data loggers at several sites in the Parker to Imperial reach. Reclamation then initiated a more comprehensive, long-term study in 2005 for the purpose of addressing how the above hydrological changes might affect riparian habitats along the Parker to Imperial reach. The objective is to monitor 372 acres (151 ha) of occupied Southwestern Willow Flycatcher habitat between Parker and Imperial Dams for 10–15 years to determine how microclimate, vegetation, and groundwater conditions might be affected by the SIAs water transfer actions. Monitoring did not commence until after diversions started; therefore, antecedent conditions are unknown and monitoring analyses focus on detecting change through time rather than comparing current conditions to a baseline. An additional objective was to compare microclimate characteristics of sites in the Parker to Imperial reach with those at flycatcher breeding areas. This chapter reports the results of this study to date.

METHODS

In 2005, we selected a subset of sites that are currently surveyed for the presence of willow flycatchers for inclusion in the habitat monitoring study. We chose 11 sites distributed along the Parker to Imperial reach that are reasonably accessible, and where we believed groundwater levels were influenced primarily by river levels and not by outside sources such as irrigation return flows. Chosen sites equated to at least 75.3 ha (186 acres) on the California side of the lower Colorado River and at least 75.3 ha (186 acres) on the Arizona side. We also chose four control sites, two above Parker Dam and two below Imperial Dam, to distinguish any changes in microclimate, groundwater, or vegetation caused by water transfer actions from those caused by fluctuations in climate or rainfall. We monitored these same 15 sites from 2005 to 2009. In August of 2006, we initiated habitat monitoring within a consistently occupied breeding site at Topock Marsh to obtain groundwater levels and patterns with which we can compare results obtained at the habitat monitoring sites.

Temperature/Humidity (T/RH) Loggers

In 2005, we deployed HOBO H8 Pro (Onset Computer Corporation, Pocasset, MA) temperature/humidity data loggers at several locations within each site selected for habitat monitoring. All loggers collected data at 15-minute intervals and were placed in inverted plastic containers and camouflaged as described in Chapter 6. All 60 logger locations selected in 2005 were retained in 2006. Two additional data loggers were installed in the Topock Marsh monitoring site in August 2006. A portion of Gila Confluence North, one of the control sites below Imperial Dam, burned in December 2006. As a result of the fire, all vegetation at one HOBO location at the site was killed, and vegetation at another HOBO location was dramatically reduced. These two HOBOs were replaced in May 2007 with HOBOs at new locations within unburned portions of the site.

HOBO loggers have been downloaded two or three times per year since installation. At each download, we examine the data to determine if there are any problems with data logger function. Data loggers are replaced whenever a potential problem with the sensors is detected. Battery level is also checked at each download, and the battery is replaced if needed.

Soil Moisture (SM) Measurements

Soil moisture beneath each HOBO logger was measured and recorded using a hand-held ThetaProbe ML2x coupled to an HH2 Moisture Meter Readout (Macaulay Land Use Research Institute, Aberdeen, UK, and Delta-T Devices, Cambridge, UK, respectively). Soil moisture measurements were collected during each presence/absence survey between 15 May and 25 July and when HOBO data were downloaded. For sites that were part of the biennial survey schedule and were not surveyed in 2009 (see Chapter 2), soil moisture measurements were collected only when HOBO data were downloaded at the beginning and end of the survey season. Soil moisture measurements, percent of the area containing inundated or saturated soil, and distance to water were recorded as described in Chapter 6.

Vegetation Measurements

We completed vegetation measurements, following the methods described in Chapter 5, at each HOBO location after flycatcher surveys were completed in late July. All HOBO loggers were also downloaded at this time. Vegetation measurements were completed at the same locations as in 2005–2008, with the exception of Gila Confluence North, where vegetation measurements were collected at the two new HOBO locations established in 2007.

Groundwater Measurements

A small-diameter shallow well, or piezometer, equipped with a pressure transducer/data logger was installed in May–August 2005 near each of the 15 sites selected for habitat monitoring to monitor groundwater levels. These 15 piezometers are described in Koronkiewicz et al. (2006a) and have been downloaded approximately three times per year since installation. One additional piezometer was installed at Topock Marsh within occupied flycatcher habitat in 2006 and has been downloaded on the same schedule as the other piezometers. At each download we check the battery level and function of the data logger. Batteries are replaced as necessary and data are examined to ascertain potential equipment malfunction.

Piezometer Replacement

The piezometer at the Gila Confluence North monitoring site was moved to a new location within the same site in July 2007 because the original station was damaged in a local brush fire. In March 2008, a new piezometer was installed at the Cibola Lake monitoring site to replace the original station, which was bulldozed sometime during the summer of 2007. Several piezometers developed consistent battery failure or other equipment malfunction during 2008. Between the summers of 2008 and 2009, we replaced the original pressure transducers (In-Situ MiniTroll Standard-P) with the newest generation of pressure transducer (In-Situ LevelTroll 500) at sites that appeared to have the worst equipment failure problems.

Data Collection

A pressure transducer/data logger equipped with a vented cable collected data hourly at each piezometer. These devices measure and record pressure of the water column present in the well, and these pressure measurements are then converted into water levels (in distance below top of casing). With vented cables and data transfer ports there is no need to correct measurements for atmospheric pressure changes, and the data can be downloaded at the wellhead without disturbing the pressure transducer in the well.

During the initial installation of the pressure transducers, as well as at each data download thereafter, water levels were manually measured in the piezometers using an electric water level sounder (Solinst-brand). These known water levels were then used to program the pressure transducer with a baseline measurement from which all other automatically recorded water levels were calculated.

We obtained additional hydrologic data from the U.S. Geological Survey (USGS) regarding streamflow and stage height in the Colorado River below Parker Dam (09427520).

Data Validation

We have identified several sources of error in the water levels recorded by the piezometers. We developed a rigorous protocol to validate each data download, determine if any errors exist with the data, and correct the raw data if possible. For consistency, we applied this data validation protocol retroactively to all data obtained since installation of the piezometers.

At each download, we compared the water level recorded by the piezometer with the manual measurement. We also checked the data logger parameters to determine whether the data logger was initialized properly. If a discrepancy >0.3 feet existed between the data logger and the manual measurement, and this discrepancy could not be accounted for and corrected by examining the setup parameters and applying an appropriate correction factor, the data were not used for analysis. Specific sources of error are identified below.

Install Drift. Because piezometers are constructed such that the pressure transducer is almost the same diameter as the inside of the piezometer, removing and inserting the pressure transducers to change batteries can change the water levels in the piezometer temporarily but drastically. This type of error was first recognized in the data following initial piezometer installation and has occurred with increasing frequency due to removing the data logger from the piezometer to change batteries at each download.

Operational Drift. In rare cases, the accuracy of the data loggers can change in the time period between downloads.

Improper Setup. After downloading data, the data loggers are reset for the next round of measurements. Conducting the startup procedure improperly can lead to errors; fortunately, most of these setup errors can be corrected. Common errors include mistakenly setting the type of reference used (i.e., recording water level elevation instead of depth), not resetting the starting water level reference value to the water level value measured manually in the field, and not restarting the data logger but continuing with the previous setup.

The errors described above did not typically prevent data from being analyzed for evapotranspiration signature (see below). The evapotranspiration analysis relies on relative changes in water level over the course of a single day, and these signatures are not affected by improper setup or correction factors.

Statistical Analyses

Microclimate

The following values were calculated for all 15 habitat monitoring sites:

- Mean soil moisture from plot center to 2.0 m from plot center
- Mean maximum diurnal temperature

- Mean minimum nocturnal temperature
- Mean daily temperature range (diurnal maximum minus nocturnal minimum)
- Mean diurnal vapor pressure
- Mean nocturnal vapor pressure

The diurnal and nocturnal periods were determined from the daily sunrise and sunset times reported for the region by the National Weather Service (2009).

These values were then calculated for all 15 sites combined and compared to the same values for territory locations at Topock Marsh. These analyses were restricted to 6 May–31 July 2008, the dates during which microclimate data were collected both within territories at Topock and at the habitat monitoring locations. One-way ANOVA tests were used to test the difference in means for the T/RH and SM values.

We assigned all plots as a control site (above Parker Dam or below Imperial Dam) or as a test site (between Parker and Imperial), then analyzed between-year differences in T/RH and SM values within these two groups using paired t-tests. We then analyzed the between-year differences among the test sites compared to the control sites using one-way repeated measures ANOVA. These analyses were restricted to 1 June–1 August. Analyses were conducted using SAS® Version 9.1 (SAS Institute 2003).

Vegetation

We analyzed the between-year differences among the test sites compared to the control sites using one-way repeated measures ANOVA for canopy height, canopy closure, percent woody ground cover, three categories of stem sizes for both live and dead stems, the percentage of each stem size category that consisted of live stems, and the percentage of the basal area within the plot that consisted of native vegetation. We also used repeated measures ANOVA to examine foliage density for live and dead vegetation at each meter interval above the ground. These analyses and all descriptive statistics were produced using SPSS® Version 16.0 (SPSS Inc.) software. We excluded vertical foliage density measurements at 5 m from plot center from the analysis so as to have comparable data across years.

Groundwater Levels

We calculated monthly high and low water levels for all piezometers. We examined monthly river flow data from below Parker Dam from 2000 to 2009 to determine whether there has been a decrease in water levels since the scheduled implementation of the change in point of diversion from Imperial Dam to above Parker Dam, which began in early 2001.

Evapotranspiration Signature. A distinct daily change in water levels occurs due to removal of water from the shallow aquifer by vegetation. Typically, water levels are lowest in the afternoon, during and following times of peak water use by plants, and water levels are highest in the morning after the shallow aquifer has been able to recharge. For the purposes of this report, we refer to this daily fluctuation as the "evapotranspiration signature." Since the 1930s, various researchers have sought to use this daily fluctuation in groundwater levels to estimate the amount of water lost from the aquifer due to evapotranspiration. Various approaches have been tried, most under highly controlled field conditions (e.g., White 1932, Gatewood et al. 1950, Bowie and Kam 1968, Hays 2003). Several studies refer to this as the "transpiration-well" method.

The transpiration-well method is based on the premise that during the day, water is lost to evapotranspiration at a faster rate than it can be replenished by the hydrostatic pressure of the aquifer. This leads to a decline in the water table between the hours of approximately 6:00 a.m. and 5:00 p.m.

Overnight, the water table rises as evapotranspiration decreases and recharge is greater than losses to vegetation. White (1932) reasoned that if water levels had no net rise or fall over the course of a day, then the net loss of water from the aquifer from evapotranspiration must equal the recharge rate. White assumed that the recharge rate was best estimated between the hours of midnight and 4:00 a.m., when very little, if any, evapotranspiration was occurring. If water levels were falling day to day, then evapotranspiration must exceed recharge, and the evapotranspiration rate would equal the daily recharge rate, plus the amount of decline in day-to-day water levels. White used the following formula (see Figure 7.1):

$$q = y(24r \pm s)$$

Where:

q = the daily evaporation rate (in inches)

y = the specific yield of the soil (unitless)

r = the hourly recharge rate between midnight and 4:00 a.m. (in inches/hour)

s = H2 - H1 = the difference in water levels on consecutive days (in inches). The value s is subtracted when water levels are rising and added when water levels are falling.

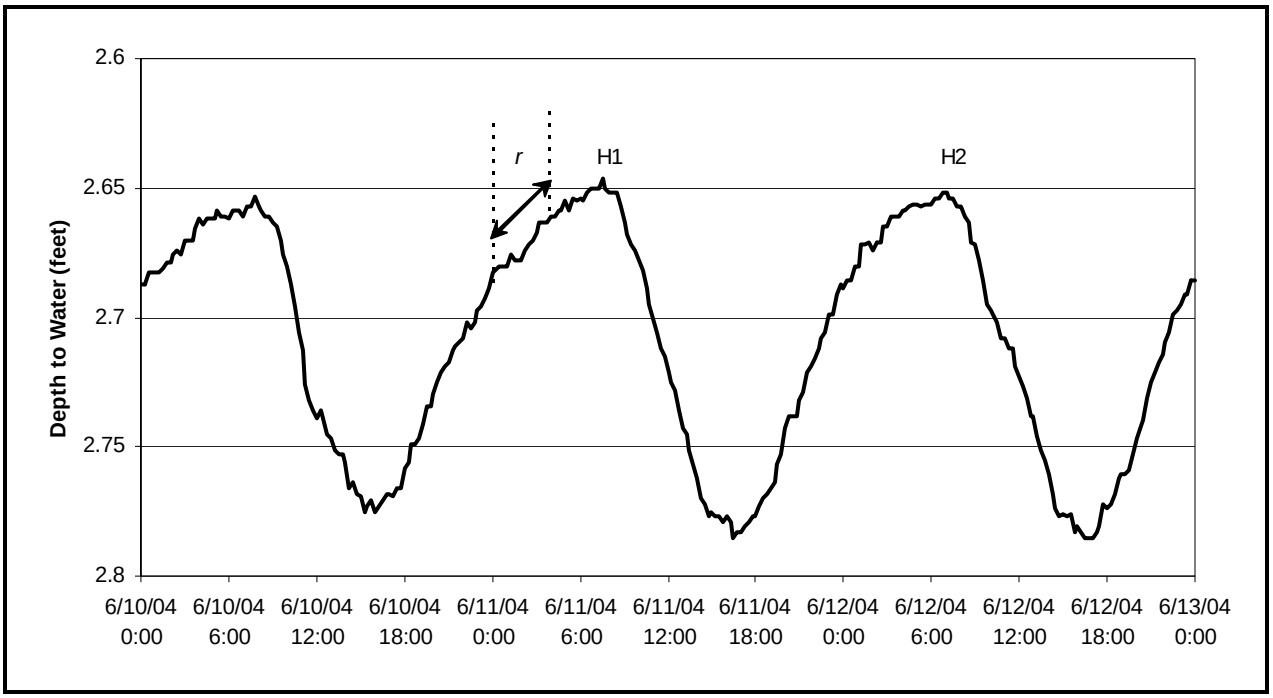

Figure 7.1. Typical daily fluctuation in groundwater levels as the result of evapotranspiration and recharge. H1 and H2 are the maximum water levels on consecutive days, while r is the recharge rate as calculated between midnight and 4 a.m.

The White formula is based on two fundamental assumptions about the shallow aquifer:

- The aquifer has a source of recharge. This source of recharge could be any surface water, either a river or a lake, or it could simply be the surrounding aquifer beyond the influence of the transpiring plants. Without some source of recharge, water levels would only decline and not rebound during the night.

- However, this source of recharge is not close or immediate enough to cause any changes in groundwater levels other than those due to evapotranspiration. Changes in overall water levels from day to day are considered to be indicative of evapotranspiration losses. If water levels rise or fall due to an outside influence (such as changes in river water levels), the calculation of evapotranspiration is rendered invalid.

We used the White formula to calculate evapotranspiration signature, with the following modifications:

- The White formula includes a term for specific yield of the soil. This term allows conversion from water level changes as observed in a piezometer to water level changes as occurring in the actual soil pore space of the aquifer. Because we are only interested in relative changes between years as a method of estimating vegetation health, we dropped the specific yield term from the White formula. Because of this, our calculations of the "evapotranspiration signature" are not directly equivalent to volumetric water loss.

- White did not specify a method for calculating daily water level changes. We have chosen to use the maximum daily water level for each day, in contrast to using the water level at any set hour. This is advantageous because the time of highest water level changes somewhat throughout the season with the changing of day length.

Because evapotranspiration is strongest during the summer months and diminishes over the winter, only the months of May–September were used for this analysis. The evapotranspiration signature reflects changes on an hourly basis, and as such is highly localized, reflecting water use by plants only in the immediate vicinity of the piezometer. The evapotranspiration signature attenuates in the aquifer the further it is from vegetation. Therefore, we limited the evapotranspiration analysis to sites where piezometers are located within the riparian vegetation that is surveyed for flycatchers (Topock Marsh, Blankenship Bend, Havasu NE, Ehrenburg, Cibola Lake, Paradise, Hoge Ranch, Clear Lake, Ferguson Lake, and Ferguson Wash).

The intent of the evapotranspiration analysis was to assess whether changes in the evapotranspiration signature over time could be used as a proxy to detect changes in vegetation density or vegetation cover resulting from changes in river level. Evapotranspiration is affected by other parameters besides vegetation density, including temperature, humidity, groundwater level, solar radiation, and wind. To be effective as a proxy for vegetation density, concurrent changes in these other parameters must be taken into account. As such, we first examined the correlation between the evapotranspiration signature as calculated from the modified White formula and mean diurnal temperature and mean daily water level in the piezometers.

In previous reports we correlated groundwater levels as measured by the piezometers with reservoir releases and soil moisture levels. We do not repeat these analyses here.

RESULTS

Temperature/Humidity Logger Maintenance

All HOBO loggers were downloaded at the beginning and end of the 2009 field season. Eight loggers had fallen to the ground over the winter because of sun damage to the logger housing. Two additional loggers that were in place over the winter had bad humidity sensors but useable temperature data, and one logger would not download. Of the HOBO loggers in place May–August 2009, three had faulty humidity data and one fell to the ground. Data from fallen loggers were not used in the analysis.

Piezometer Installation and Maintenance

The original data loggers (miniTroll models) were replaced with LevelTroll models at Topock Marsh Paradise, Hoge Ranch, Ferguson Wash, and Gila Confluence North in March 2009. Table 7.1 lists details on installation parameters for all piezometers.

All of the data loggers except for Ehrenberg have experienced multiple data breaks over their lifetime due either to battery failure or equipment malfunction. The incidences of battery failure are chronic with all of the originally installed equipment and continuously disrupt data collection. As a result, we have started replacing batteries in the original equipment at each download session regardless of the battery level reading. The LevelTroll models have internal batteries with a manufacturer-reported minimum lifespan of 5 years.

Data Validation

A total of 151 download periods were assessed using the data validation protocol. Of these, 109 download periods (72%) required no correction. An additional 27 download periods (18%) had identifiable errors and a correction factor was applied to the data. Data from 15 download periods (10%) were unable to be validated, and the data were deemed unusable for analysis. Of the 27 download periods with correctable errors, 7 experienced install drift and 3 experienced operational drift. Seventeen download periods required corrections due to improper setup, primarily of reference points. Improper setup errors also caused all 15 of the download periods determined to be unusable; most of these instances resulted from the combination of setup errors and equipment malfunction.

The data validation procedure allows most of the recorded data to be corrected and deemed usable and reliable for analysis; the larger challenge has been equipment loss (Cibola Lake and Gila Confluence North) or outright failure. The new model data logger installed at Hoge Ranch proved to be defective and collected no data in 2009. In addition, hardware communication, software compatibility, and user error issues rendered 2009 data from the new model data loggers unusable at Paradise, Ferguson Wash, and Gila Confluence North. In the September 2009 download, data loggers from Blankenship Bend, Havasu NE, Three Fingers Lake, and Mittry West had to be removed and shipped to the manufacturer for data retrieval. All four data loggers have been deemed by the manufacture to be defective and unrepairable.

Table 7.1. Summary of Piezometer Construction and Data Collection at Habitat Monitoring Sites, Lower Colorado River, 2005–2009*

Site	Depth (ft)	Stickup height (ft)	Date installed	Data breaks	Distance (ft) from habitat
Topock Marsh	INA	2.5	13-Aug-06[1]	Aug 2007–Feb 2008[2] Jun 2008–Mar 2009	Within

* INA = information not available, N/A = not applicable.

[1] Original piezometer replaced with new model LevelTroll.

[2] Dates differ from those presented in previous reports due to data validation.

[3] Piezometer destroyed by clearing activity between February and July 2007; replaced 27 March 2008; stick-up height applies to new piezometer.

[4] Location of original piezometer burned in December 2006; piezometer replaced on 5 July 2007; stick-up height applies to new piezometer.

Microclimate

2009 Microclimate Descriptive Statistics

Soil moisture, temperature, and vapor pressure parameters from the 15 study sites monitored in 2009 exhibited substantial variation among sites (Table 7.2). Soil moisture varied by a factor of four among the 2008 study sites, from a low of 227.4 mV at Havasu NE to a high of 917.6 at Great Blue Heron.

Mean maximum diurnal temperatures ranged from a low of 37.4°C at Clear Lake and a high of 50.8°C at Three Fingers Lake. Mean minimum nocturnal temperatures ranged from a low of 18.4°C at Three Fingers Lake to a high of 22.4°C at Ferguson Lake. Mean number of 15-minute intervals above 41°C

each day varied from 1.8 at Rattlesnake to 24.7 at Cibola Lake. Mean daily temperature range varied from 16.0°C at Clear Lake to 32.3°C at Three Fingers Lake.

Mean diurnal vapor pressure was lowest at Three Fingers Lake (1,098.2 Pa) and highest at Rattlesnake (2208.5 Pa). Mean nocturnal vapor pressure was lowest at Three Fingers Lake (1161.2 Pa) and highest at Rattlesnake (1923.6 Pa).

Between-year Comparisons of Microclimate Characteristics

All microclimate characteristics varied significantly over time at test sites (Ehrenberg, Three Fingers Lake, Cibola Lake, Clear Lake, Walker Lake, Ferguson Lake, Ferguson Wash, Great Blue Heron, Hoge Ranch, Paradise, and Rattlesnake; Table 7.3). At control sites (Blankenship Bend, Havasu NE, Mittry West, and Gila Confluence North), only mean minimum nocturnal temperature varied significantly over time. Neither test nor control sites showed a unidirectional change in any of the microclimate measures over time. The changes over time differed between test and control sites for soil moisture, mean maximum diurnal temperature, and daily temperature range (right-most column of Table 7.3). Between 2005 and 2006, soil moisture decreased more dramatically at control sites than at test sites, while between 2007 and 2008, soil moisture decreased at control sites but rose at test sites. Between 2007 and 2008, both mean maximum diurnal temperature and mean daily temperature range increased at test sites but decreased at control sites.

Comparison of Parker/Imperial to Topock Marsh: Microclimate

Topock Marsh was cooler and more humid than habitat monitoring sites but did not differ from habitat monitoring sites in average soil moisture (Table 7.4).

Table 7.4. Comparison of Microclimatic Variables at Habitat Monitoring Sites to Territories at Topock Marsh, 2009*

Response variable	Habitat Monitoring Sites	Topock Marsh	*P*
N (Temp./Humidity Sensor Arrays)	57	14	N/A
Soil Moisture			
Mean soil moisture (mV)	674.5 (35.6)	657.3 (73.4)	0.832
Temperature			
Mean maximum diurnal temperature (°C)	44.1 (0.8)	41.0 (1.5)	0.077
Mean minimum nocturnal temperature (°C)	20.6 (0.2)	19.2 (0.4)	0.002
Mean daily temperature range (°C)	23.5 (0.9)	21.8 (1.3)	0.358
Humidity			
Mean diurnal vapor pressure (Pa)	1660.5 (56.1)	2278.0 (87.8)	<0.001
Mean nocturnal vapor pressure (Pa)	1535.0 (37.1)	1891.0 (62.2)	<0.001

* Soil moisture and temperature/humidity values are means (standard error in parentheses). N/A = data not available or not applicable. The analysis was restricted to 6 May–31 July 2009.

Vegetation Measurements

Vegetation characteristics varied widely both between and within the selected habitat monitoring sites (Table 7.5). Average canopy height ranged from 3.3 m (Three Fingers Lake) to 11.8 m (Ehrenberg), and average canopy closure ranged from 63.7% (Cibola Lake) to 96.2% (Walker Lake). Measures of other habitat characteristics were similarly variable. Vertical foliage profiles for each site are shown in Figure 7.2. Sites typically exhibited the densest foliage within 3–5 m of the ground, and the majority of vegetation within 2–3 m of the ground typically consisted of dead branches.

Between-year Comparisons of Vegetation Characteristics

Repeated measures ANOVA showed an overall between-year difference in canopy closure ($P < 0.001$), woody ground cover ($P < 0.001$), number of live stems < 2.5 cm and 2.5–8 cm dbh ($P = 0.020$ and $P = 0.041$, respectively), number of dead stems <2.5 cm and 2.5–8 cm dbh ($P = 0.022$ and $P = 0.002$, respectively), percentage of live stems <2.5 and 2.5–8 cm dbh ($P < 0.001$ and $P = 0.002$, respectively), and percent native basal area ($P = 0.013$) for all plots combined (Table 7.6). The only variables that exhibited a consistent change across time were percentage of live stems <2.5 cm dbh, which declined steadily from 2005 to 2009, and percentage of live stems 2.5–8 cm dbh, which was lower in 2008 and 2009 than in the three preceding years. Woody ground cover was the only variable for which there was a significant interaction ($P = 0.019$) with location (test vs. control sites), meaning the changes in all the other variables between years among test sites was not significantly different from the change at control sites. Average woody ground cover increased at control plots between 2005 and 2006 and then decreased in 2007, while it did not change at test plots across those years.

Repeated measures ANOVAs for vertical foliage in each meter interval showed a between-year difference in live vegetation in the fourth meter interval above the ground ($P = 0.048$) and between-year differences for the first, second, third, and fourth meter intervals above the ground for dead vegetation ($P < 0.001$ for each interval). In all four intervals, density of dead vegetation was higher in 2008 than in 2007. There was a significant interaction ($P = 0.039$) between live vertical foliage density and location (test vs. control sites) for the fourth meter interval, but there was no clear pattern, with density generally increasing at control plots in years it decreased at test plots, and vice versa. There was also a significant interaction ($P = 0.001$) between dead vertical foliage density and location for the first meter interval, with the density of dead vegetation increasing more in 2007 and 2008 at control plots relative to test plots. The percentage of live vegetation in each meter interval differed between years only in the fourth meter interval ($P = 0.005$); in this case, the live percentage was lower in 2008 than in 2007.

Groundwater Monitoring

Overview of Piezometer Groundwater Levels

Data collected from fall 2005 to spring 2007 are relatively complete with sporadic recording errors. Many data from 2008 and 2009 are unreliable and eight sites have no data for 2009 (see Table 7.1). The sites that have remained functional (Havasu NE, Ehrenberg, Three Fingers Lake, Walker Lake, Great Blue Heron, and Mittry West) throughout most of the study period show similar patterns across years.

Daily and weekly cycles are still apparent in the piezometer hydrographs. General daily trends include low water levels during the afternoon hours when vegetation water demands and evapotranspiration are greatest and high water levels in early morning hours. General weekly trends follow the changes in river water levels due to power generation and water delivery demands, with low levels on weekends and higher levels in the middle of the week.

In addition to daily and weekly cycles, a seasonal trend is observed in hydrographs in a majority of the sites. The data trend remains similar to that of previous years, although some sites had slightly higher and lower maximum and minimum water levels. For most of the sites between Parker and Imperial Dams, the lowest water levels occurred in December through February, and highest water levels occurred in April (Table 7.7). Topock Marsh, Havasu NE, Walker Lake, and Gila Confluence North did not display this seasonal trend. The shallowest average monthly water level occurred at Mittry West in April and the deepest occurred at Paradise in December. Seasonal changes in water levels range from 0.94 feet at Walker Lake to almost 3.5 feet at Ehrenberg. Hydrographs for all piezometers are included in Appendix E.

Planned Declines in Parker Releases –Average monthly river flow data below Parker Dam from 2000 to 2009 (Table 7.8) show declines in reservoir releases for most months. While there is variation, average monthly flow throughout the year decreased from 2001 (the year prior to the scheduled change in point of diversion) to 2009 except for January and March, the only months that experienced an increase of average flow for 2009. The percent decrease from 2001 to 2009 was lowest in April (6.4%), greatest in December (35.9%), and ranged from 21.5 to 32.2% in June–August. During the period when groundwater levels were recorded (2005–2009), overall annual river flows did not decrease.

Table 7.7. High and Low Average Monthly Water Depths Recorded at Piezometers at Habitat Monitoring Sites, 2005–2009

Location	Shallowest water level (ft bgs)	Month occurred	Deepest water level (ft bgs)	Month occurred

Evapotranspiration Signature

Of the10 sites within the riparian vegetation that is surveyed for flycatchers, 6 (Topock Marsh, Blankenship Bend, Havasu NE, Cibola Lake, Paradise, and Hoge Ranch) yielded usable evapotranspiration signature data over multiple years (Table 7.9). The evapotranspiration signature was calculated for these six piezometers; however, several anomalous patterns became apparent in the piezometers along the river (Blankenship Bend, Havasu NE, Cibola Lake, Paradise, and Hoge Ranch). Notably, sharp reductions in the evapotranspiration signature were occurring with regularity every seven days, suggesting some control other than a seasonal change. Upon close inspection of the hydrographs, we realized that the intraday groundwater level changes in the piezometers were influenced much more strongly by river water levels than anticipated. As reported above, the river experiences a strong weekly pattern in water levels, with low levels on the weekend and higher levels during the week. The sharp rise and fall of the river level during the transitions between week and weekend overwhelmed any water level changes due to the evapotranspiration of water by riparian vegetation. The White formula requires that the source of recharge be distant and consistent; the recharge provided by the river is too strong and immediate to allow use of the White method at these piezometers.

The piezometer within Topock Marsh was deemed the sole location at which the recharge source appeared to be consistent enough to meet the assumptions for the White formula, and we limited further analysis of the evapotranspiration signature to this location. Complete piezometer and temperature data were available at Topock Marsh only for May–August in 2007 and 2009.

Over the course of each season, the White evapotranspiration signature increased steadily while the groundwater level in the aquifer steadily declined (Figures 7.3 and 7.4). The linear regression for mean diurnal temperature versus evapotranspiration signature showed a weak, direct correlation, with coefficients of determination of 0.41 and 0.30 for 2007 and 2009, respectively (Figures 7.5 and 7.6). The linear regression for mean daily water level versus evapotranspiration signature showed a strong, direct correlation, with a coefficient of determination of 0.67 and 0.95 for 2007 and 2009, respectively (Figures 7.7 and 7.8). The direct relationship between depth to water and evapotranspiration (i.e.; the deeper the water dropped over the season, the greater the evapotranspiration from the vegetation) is the opposite of the relationship indicated in the literature, which shows decreasing evapotranspiration with increasing depth to groundwater (e.g., Blaney 1954).

The remaining four piezometers within flycatcher habitat (Ehrenberg, Clear Lake, Ferguson Lake, and Ferguson Wash) yielded water levels that did not consistently reflect daily changes in evapotranspiration. This lack of signature is likely the result of imperfect or delayed communication with the aquifer, caused by tight sediments surrounding the well screen, or possibly plugged well screens. Negative values shown in Table 7.9 are indicative of those piezometers that do not follow the typical daily signature caused by evapotranspiration losses from the aquifer. In these cases, either changes in water levels are significantly delayed (resulting in a reversal of the evapotranspiration signature) or show no daily pattern at all (resulting in a random evapotranspiration signature).

DISCUSSION

Microclimate

Comparison of Parker/Imperial to Topock Marsh

In each year from 2005 to 2009, the 15 habitat monitoring sites consistently had warmer temperatures, greater daily temperature range, and lower humidity than occupied territories at Topock Marsh. In addition, soil moisture within the habitat monitoring sites was consistently lower than that recorded within occupied territories at Topock in 2005–2007. Soil moisture at the habitat monitoring sites did not differ from that measured within occupied territories at Topock in 2008 and 2009. This may be the result of a change in site selection methods at Topock, with soil moisture readings collected in 2008 and 2009 at a point within 20 m of each territory center, regardless of whether the territory remained occupied throughout the season or had a breeding pair, thus resulting in measurements being taken in a wider range of habitat conditions. The hot, dry conditions at the habitat monitoring sites may contribute to these areas not being occupied by resident flycatchers. Because the relationship of microclimate conditions between the habitat monitoring sites and Topock Marsh is well established, we recommend discontinuing this analysis in future years.

Between-year Comparisons of Microclimate Characteristics

Comparisons of microclimate characteristics among years in 2005–2009 at the habitat monitoring sites indicated hotter and more humid conditions in 2006 than in the other years and cooler conditions in 2009. These interannual changes were similar between test and control sites, suggesting that these changes were regional rather than being influenced by local conditions. The interannual changes in soil moisture in 2005–2006 and 2007–2008 were not similar between test and control sites, with soil moisture declining

more sharply at the control sites. This suggests that local conditions, in addition to regional climate, may have influenced soil moisture. However, the role of river flows in influencing soil moisture is unclear, given that no strong relationship was found between piezometer levels and soil moisture (McLeod and Koronkiewicz 2009) and the lack of consistent piezometer data at many sites in 2008 and 2009. Mean daily temperature range and mean maximum diurnal temperature were higher at test sites but lower at control sites in 2008 versus 2007. These metrics decreased sharply in 2009 at both test and control sites, presumably in response to the unusually cool climate conditions during portions of summer 2009. Thus, we have not seen any consistent patterns in the changes in microclimate characteristics at test versus control sites that could be attributed to changes in river flows.

Vegetation

Between-year differences across all sites were noted for many variables, but the only ones that showed unidirectional trends were the percentage of live stems <2.5 cm dbh and the percentage of live stems 2.5–8 cm dbh, both of which declined over time. The percentage of live stems should be less susceptible to observer variation than the absolute stem counts, and it is likely these data represent a true decline in the percentage of live stems. The decline occurred in both test and control sites and could be the result of regional drought.

Few variables showed changes that were specific to control or test sites. Ground cover did not differ between 2005 and 2007 at test locations but increased at control plots in 2006 and then decreased in 2007. It is not clear whether this represents actual changes in the amount of woody ground cover or whether it is a result of observer variation. Vertical foliage counts did not show any consistent differences between control and test locations.

The pooling of all sites into a test vs. control analysis may obscure changes in vegetation at specific sites. For example, one vegetation plot at Ehrenberg contained a significant coyote willow component (98% of the total basal area) in 2005. The willow gradually died over the next several years until no live willow remained in 2009. Most of the vegetation along the LCR, including at the sites selected for habitat monitoring, consists primarily of tamarisk, which is less sensitive than willow to changes in water availability. Measurable changes in overall vegetation as a response to reduced groundwater levels may take several years to develop in tamarisk, or the tamarisk may change very little if at all.

It has become apparent, after measuring the same vegetation plots for several consecutive years, that stem counts in very dense vegetation are inherently inaccurate and imprecise and can vary widely from year to year when there has likely been no appreciable change in stem density. Repeatability of stem counts depends on having a plot of fixed size. Each plot is divided into quadrants, with a rope having the 5-m distance (the edge of the plot) clearly marked extended in each cardinal direction from plot center. It can be nearly impossible to extend the rope flat or straight, introducing variability into the size of the plot. Even more problematic than this, however, it the inability of the observers, in very dense vegetation, to see the cardinal ropes from the center of the quadrant or to see the center of the plot from the edge to be able to envision an arc connecting the ends of two adjacent cardinal ropes and delineating the edge of the circular plot. Observers vary widely in their ability to estimate distance, and when reference points are not visible, it is very difficult to determine whether a stem near the edge of the plot falls within the plot or not. In 2009, we explicitly instructed observers to use a measuring tape to determine the distance from plot center for any stem for which inclusion in or exclusion from the plot seemed questionable. This method should help reduce difficulties in producing repeatable stem counts but still depends on observers being able to tell when they are near the edge of the plot. Another factor that inhibits accurate stem counts in dense vegetation is the difficulty in keeping track of which stems have been counted already and which have not. In 2009, we began using chalk to mark stems that had already been counted to try to minimize omission or double-counting of stems.

Given the difficulties in producing repeatable stem counts, absolute stem counts are likely not a suitable metric for detecting subtle changes in vegetation. The proportion of live stems may provide a more sensitive metric by which to detect change; the accuracy of this measure depends only on each observer counting live stems in a manner consistent with how s/he counts dead stems. Similarly, the proportion of live vertical foliage is likely to provide a more sensitive measure of changes in vegetation than do the absolute vertical foliage counts.

The detection of changes in vegetation as the result of the diversion of water at Parker rather than Imperial Dam is further hampered by the complete lack of vegetation measurements prior to the beginning of the diversion in 2002. Vegetation measurements did not commence until 2005, by which time it is possible that some changes in vegetation, particularly in sensitive species such as coyote willow, had already occurred. Other methods, such as analysis of satellite imagery, would have to be used to detect any changes in vegetation that might have occurred prior to 2005.

Groundwater Levels

Piezometer Groundwater Levels

In previous years we examined correlations between piezometer levels and reservoir operations. Groundwater levels in the piezometers between Parker and Imperial Dams, with the exception of Walker Lake, showed strong linear relationships with Parker Dam releases, which are in turn related in a nearly linear fashion to river stage (McLeod and Koronkiewicz 2009). Reclamation (2000) estimated the expected change in river stage between Parker and Imperial Dams that would result from a 400,000 acre-foot reduction in releases from Parker Dam. In a previous report (McLeod et al. 2007), we used this expected reduction in river stage in combination with regression equations developed from the piezometer measurements to predict the corresponding change in groundwater level below each habitat polygon. Thus, releases from Parker Dam can be used to predict the groundwater level beneath the habitat polygons, and the piezometers are no longer needed for measuring groundwater levels as related to river operations.

In general, the daily, weekly, and seasonal cycles observed in previous years' data are still visible in 2009 data. The early morning rise and afternoon drop in water level is attributed to daily evapotranspiration; the mid-week rise and weekend drop of water levels is attributed to river operations. River operation is the primary contributing factor for the seasonal fluctuation in groundwater levels observed in the hydrographs for sites between Parker and Imperial Dams. Seasonal trends can even be detected in the manual measurements at those sites lacking in recent data logger data (Blankenship Bend, Paradise, Clear Lake, and Ferguson Lake).

Several anomalous hydrograph features deserve discussion:

Blankenship Bend, Cibola Lake, and Gila Confluence North – The hydrograph for three piezometers clearly show where equipment has malfunctioned. The Blankenship Bend data logger began to act erratically in the summer of 2007 and has not collected reliable data since. The pressure transducer finally failed entirely and has been removed. The hydrograph for Gila Confluence North has not been normal since the piezometer was moved to the new location after the fire. Even though the equipment has been replaced at this site, the hydrograph indicate the piezometer may not be communicating with the aquifer and most likely needs to be reinstalled. Cibola Lake displayed seasonal fluctuations similar to those observed at other piezometers between Parker and Imperial Dams until the well was destroyed by ground clearing activities. Water levels have remained

essentially flat for the monitoring period since installation of the replacement piezometer. This well may need a re-install or warrant a change in location closer to the selected habitat area.

Walker Lake – Since two apparent inundations in the summer of 2005, the water level at Walker Lake has steadily decreased through the period of record. The seasonal signature continues to be strong and appears to match the pattern at most of the piezometer locations between Parker and Imperial Dams. Though there are breaks in the 2008 and 2009 data, the downward trend and the seasonal highs and lows can be seen. The hydrograph displays periods of spiked water levels on several occasions, including the winter and fall of 2006, fall of 2007, and summer of 2008, indicating Walker Lake may be prone to flashy response time.

Mittry West – While the hydrograph for the Mittry West piezometer was almost flat from installation through December 2005, the data show a seasonal trend in 2006–2008, with peak water levels occurring in the spring of each year. Weekly fluctuations and daily fluctuations are not as apparent on the rising leg of the seasonal curves, but reappear on the declining leg of the curves. A second peak in water levels occurred during the summer of 2007. Apparent inundations have occurred at Mittry West in the spring of 2006, 2007, and 2008 and in winter 2008. Water levels in Mittry West may be influenced by the All American Canal, which is adjacent to the site.

Only 1 of the original 16 piezometers is still functioning, and it has become apparent that the original piezometer data loggers have exceeded their lifespan. The relationship between groundwater levels and river operations has been established, and the strong influence of daily changes in river discharge on groundwater levels renders the piezometer data unsuitable for tracking changes in evapotranspiration over time. Thus, we recommend removing all the piezometers except the one at Topock Marsh, which may be useful in tracking changes in water levels at part of planned water deliveries to a portion of the flycatcher habitat (see Chapter 8).

Correlation of Piezometer Groundwater Levels with Soil Moisture Measurements

In previous years we correlated piezometer ground water levels and soil moisture measurements and found no strong linear relationship. The strongest relationships were found at sites that had the highest soil moisture values. This suggests that at sites were soil moisture is low, surface soil moisture content is not influenced by groundwater levels, and soil moisture measurements are unlikely to reflect any changes in water availability caused by changing river levels. We recommend discontinuing soil moisture measurements at Havasu NE, Cibola Lake, Clear Lake, Ferguson Wash, and Gila Confluence North, where soil moisture values are consistently below 600 mV.

Evapotranspiration Signature

The evapotranspiration signature at Topock Marsh was weakly correlated with temperature; i.e., increasing temperature was associated with an increased evapotranspiration signature. However, temperature was also correlated with depth to groundwater, because both increased over the May–August period each year. Data from the fall months—when plants are still active, depth to groundwater is high, but temperatures are dropping—may be helpful in distinguishing the effects of temperature from those of depth to groundwater. Fall data are lacking from 2007 but may be available from 2009 after the temperature/humidity loggers are downloaded in spring of 2010.

The evapotranspiration signature at Topock Marsh was directly related to depth to groundwater, rather than showing the inverse relationship demonstrated in the literature. We therefore suspected that the relationship was coincidental, rather than causal. To determine why evapotranspiration might be

increasing in the face of a lowered water table, we deconstructed the White formula. We determined that two fundamental assumptions of the formula likely had been glossed over in previous applications reported in the literature:

- The recharge of the aquifer as measured at the piezometer is driven by basic groundwater hydraulics, and is a function of the aquifer material and the hydraulic gradient between the source of recharge (surface water) and the piezometer. The aquifer material does not change over the season, but the hydraulic gradient does. We realized that as water levels dropped through the season at the piezometer, that lowering of the water table likely affected the overall hydraulic gradient, increasing recharge to the aquifer. The effect of this increasing recharge cannot be controlled for or easily extracted from the evapotranspiration signature.

- Similarly, we realized that the source of recharge to the aquifer, specifically the standing water within Topock Marsh, might also change in location or amount through the season. This would cause a change in hydraulic gradient as well.

These hydraulic effects had not been considered in previous literature on the technique of using the evapotranspiration signature; those studies focused largely on monthly snapshots of evapotranspiration with an eye towards estimating gross volumes of water used by riparian vegetation, without being concerned with stability of the formula through the season. While these findings do not invalidate the White technique, we found that being unable to correct for the changing hydraulic effects likely rendered ineffective the use of the evapotranspiration technique to track vegetation changes over time.

Chapter 8

SURFACE HYDROLOGY, MICROCLIMATE, AND VEGETATION MONITORING: TOPOCK MARSH

INTRODUCTION

Monitoring of Southwester Willow Flycatcher populations at Topock Marsh began in 1997, and data on number of flycatcher pairs and nest success are available for 1998–2008. The breeding population at Topock declined from a high of 29 pairs in 2004 to fewer than 10 pairs in 2007 and 2008. This decline prompted concern from USFWS about the flycatcher population at Topock, which was presumed to be the likely source population for any flycatchers that would colonize restoration areas on the lower Colorado River. USFWS and Reclamation initiated discussions after the breeding season of 2008 to identify habitat enhancement measures that could be implemented at Topock Marsh in an attempt to raise the number and productivity of flycatchers.

The affinity of breeding Southwestern Willow Flycatchers with standing water and saturated soil is noted consistently in the literature (e.g., Johnson et al. 1999, Munzer et al. 2005, McLeod et al. 2008, Graber and Koronkiewicz 2009b), and flycatcher nests along the Middle Rio Grande that were above inundated or saturated soil all season produced more young per successful nest than nests that were above dry soil all season (Moore and Ahlers 2008). Because of the influence of surface water on flycatcher occupancy and productivity, USFWS and Reclamation developed a plan to pump water into a portion of the flycatcher habitat at Topock.

Two adjacent areas, known as In Between and 800M, have had declining numbers of flycatchers in recent years, with the number of breeding pairs declining steadily from 10 in 2004 to 0 in 2008. These adjacent areas were selected as the location for habitat enhancement via supplemental water delivery because these areas have supported breeding willow flycatchers within the last several years and the vegetation in the area has not changed markedly since the sites were occupied (see Chapter 5 for analysis of vegetation data from formerly occupied nest sites). The addition of surface water and saturated soil to this area may make it more attractive to flycatchers and may increase nest success and productivity of any flycatchers that nest in the area. In addition, widespread inundation of the area may make portions of In Between, 800M, and the surrounding area that typically have been dry during surveys since 2003 and not occupied by flycatchers more suitable for flycatcher occupancy.

Supplemental water delivery is not expected to commence until early 2010. We monitored hydrological, microclimate, and vegetation conditions at In Between, 800M, and the adjacent area of Pierced Egg in 2009 to assess baseline habitat conditions. Similar monitoring will be completed in 2010, and data will be compared to those collected in 2009 to assess the effects of supplemental water delivery on hydrology, microclimate, and vegetation in the target area.

METHODS

Surface Water Mapping

Beginning in early March 2009 and continuing through early August, we visited In Between, 800 M, and Pierced Egg at approximately weekly intervals. During each visit, we traversed trails throughout each site

and used GPS and aerial photographs to map the extent and depth of surface water within the sites. At the conclusion of each weekly visit, we compiled our GPS points and field notes to prepare a hardcopy map of the sites, with areas of surface water and saturated soils delineated on the map and indexed to a key detailing the nature (e.g., pig wallow, open marsh, flooded forest) and depth of each wet area. All hardcopy maps were digitized after the field season using ArcGIS. From the digitized shapefiles, we calculated the percentage of the target area that contained surface water at each visit.

Microclimate

The In Between, 800M, and Pierced Egg polygons were stratified into use (occupied by flycatchers) and non-use (unoccupied by flycatchers) areas, as observed in 2003–2008. Use areas tend to be wetter than non-use areas and thus are presumably low-lying and more likely to be affected by water delivery into the habitat. We excluded the cattail marsh in the center of the 800M polygon from either the use or non-use areas. We superimposed a 25 x 25-m grid on a GIS software shapefile of the use and non-use areas, numbered the grid blocks, and selected blocks using a random number generator. We used the centroid of the selected block as the sample point and located each point in the field by navigating to the given coordinates using a Rino 110 GPS unit. We used HOBO H8 Pro data loggers (see Chapter 6) to record temperature and humidity at each sample point at 15-minute intervals. We determined the exact location of each HOBO unit by means of random number sequences as described in Chapter 6. Each logger remained in place until the end of the flycatcher breeding season. We had originally intended to leave the loggers in place over the winter but decided to remove them at the end of the season after experiencing a large number of losses among the HOBO units that were left in place at occupied territories over the 2008–2009 winter. We collected soil moisture readings, as described in Chapter 6, below each data logger at bi-weekly intervals.

Vegetation

In August 2009, at the end of the flycatcher breeding season, we collected vegetation measurements at each HOBO logger location. Vegetation plots were centered on the logger, and we collected the vegetation measurements described in Chapter 5, with the exception of stem counts. Given the relatively short time span between planned implementation of water delivery (March 2010) and the subsequent vegetation measurements (August 2010), any responses in vegetation are more likely to be apparent in canopy closure and vertical foliage density than in stem counts.

Data Analyses

Microclimate

Microclimate data were summarized as described in Chapter 6. All data were summarized separately for occupied and unoccupied areas.

Vegetation

Vertical foliage data were summarized as described in Chapter 5. Percent native vegetation was calculated as the percent of the foliage hits that consisted of native vegetation. We used the average nest height (3.78 m) recorded at In Between, 800M, and Pierced Egg from 2003 to 2008 to delineate the below, at, and above nest height categories. All data were summarized separately for occupied and unoccupied areas.

RESULTS

Surface Water Mapping

We mapped surface water at weekly intervals from 10 March to 8 August. The percentage of the site that was inundated rose rapidly in late March and early April to a high of almost 45% and then declined just as rapidly in May (Figures 8.1 and 8.2). By early June, <5% of the site had surface water.

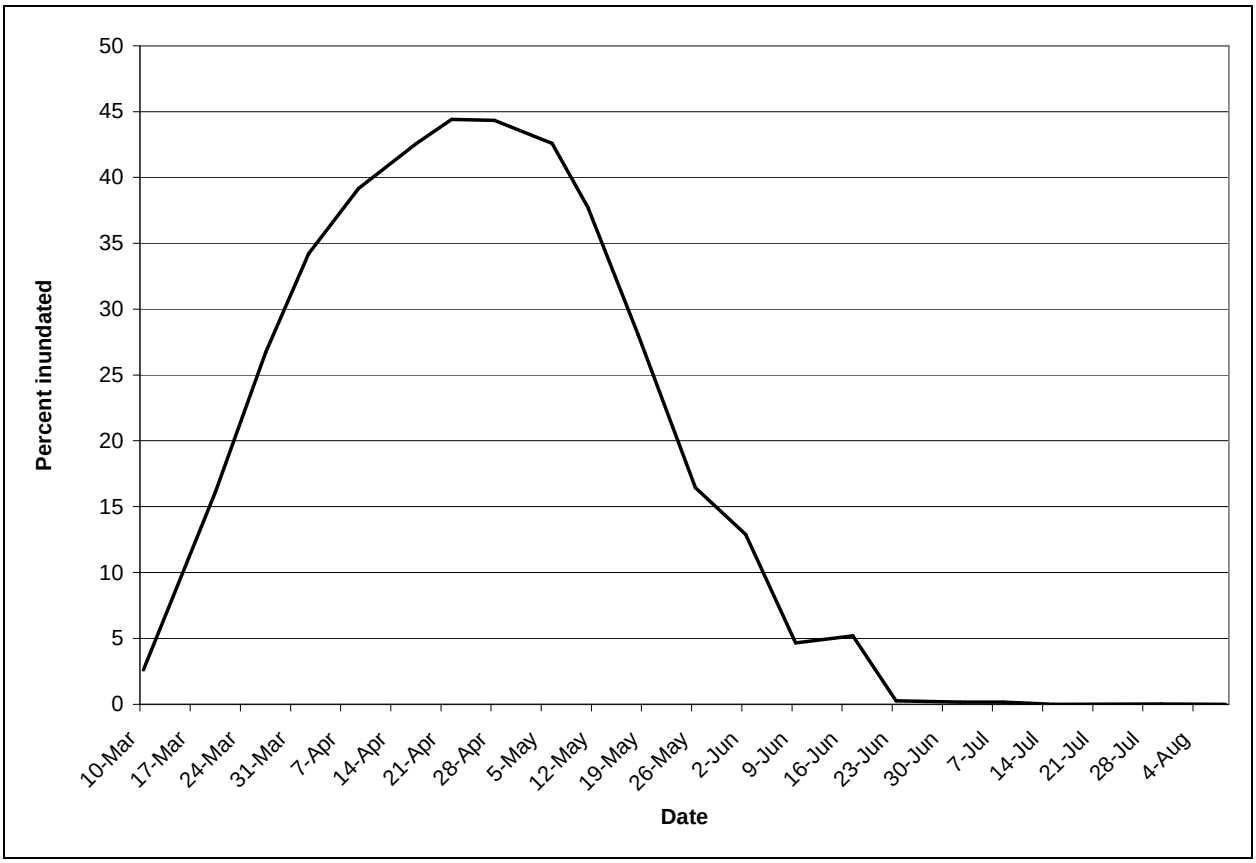

Figure 8.1. Percentage of In Between, 800M, and Pierced Egg, combined, that was inundated in March–August 2009.

Microclimate

We deployed 15 HOBO loggers in use areas and 17 loggers in non-use areas between 10 March and 9 April. One use logger and three non-use loggers failed to collect data. Soil conditions became progressively drier throughout the season for both the use and non-use areas, while vapor pressure values showed the typical rise seen in July with the onset of summer monsoons (Tables 8.1 and 8.2). Qualitative comparison of the use and non-use areas shows that the use area had greater soil moisture, lower and more moderate temperatures, and higher humidity consistently through the season, as would be expected (see McLeod et al. 2008).

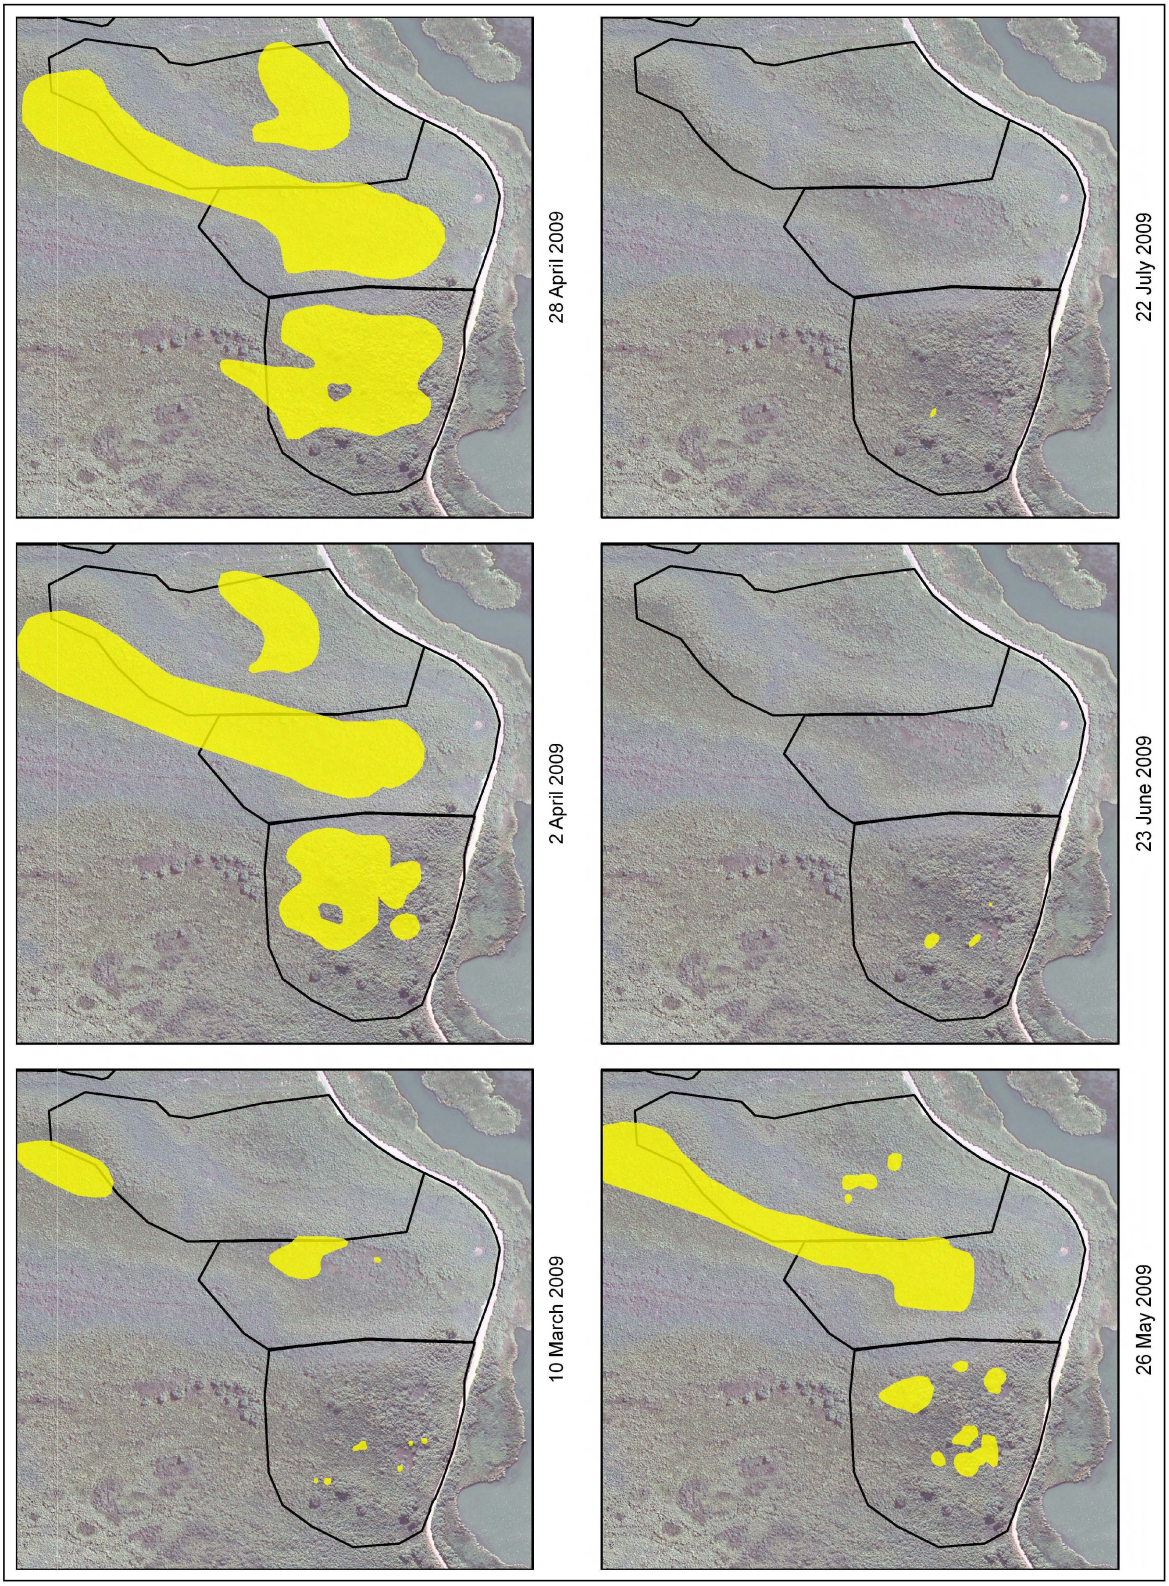

Figure 8.2. Extent of surface water within In Between, 800M, and Pierced Egg at approximately monthly intervals, March–July 2009.

Table 8.1. Microclimate Measures at Topock Hydrology Monitoring Sites – Use Area (n = 14), 2009*

Microclimate Measure	May 12–31	June 1–15	June 16–30	July 1–15	July 16–31	August 1–15

AR063576

Vegetation

We collected vegetation data at all 15 use and 17 non-use locations. Vegetation characteristics are summarized in Table 8.3, and vertical foliage profiles for use and non-use locations are shown in Figures 8.3 and 8.4, respectively. Vegetation characteristics are typical of those documented in dense, tamarisk stands at Topock Marsh in previous years (McLeod et al. 2008), with dense canopy closure and a small percentage of native vegetation. As would be expected (McLeod et al. 2008), canopy height was greater in the use area than in the non-use area.

Table 8.3. Summary of Vegetation Characteristics within Portions of Topock Marsh Selected for Habitat Enhancement, 2009*

Parameter	Use (n=15)	Non-use (n=17)
Average canopy height (m)	6.7 (0.3)	5.6 (0.3)
	4.7 –8.5	3.3 –8.0
% total canopy closure	96.6 (0.6)	94.0 (0.9)
	91.1 –100.0	82.3 –99.0
% woody ground cover	22.1 (5.5)	26.9 (4.3)
	3.8 –75.0	5.3 –65.0
Live vertical foliage (hits) below nest	2.2 (0.5)	5.3 (0.9)
	0 –6.9	1.6 –14.3
Live vertical foliage (hits) at nest	2.3 (0.3)	4.1 (0.4)
	0.3 –4.4	0.9 –6.6
Live vertical foliage (hits) above nest	11.8 (0.9)	6.4 (1.0)
	4.4 –17.1	0.4 –15.4

* The selected area was stratified into areas occupied and unoccupied by flycatchers in 2003–2008. Data are presented as mean, standard error, and range.

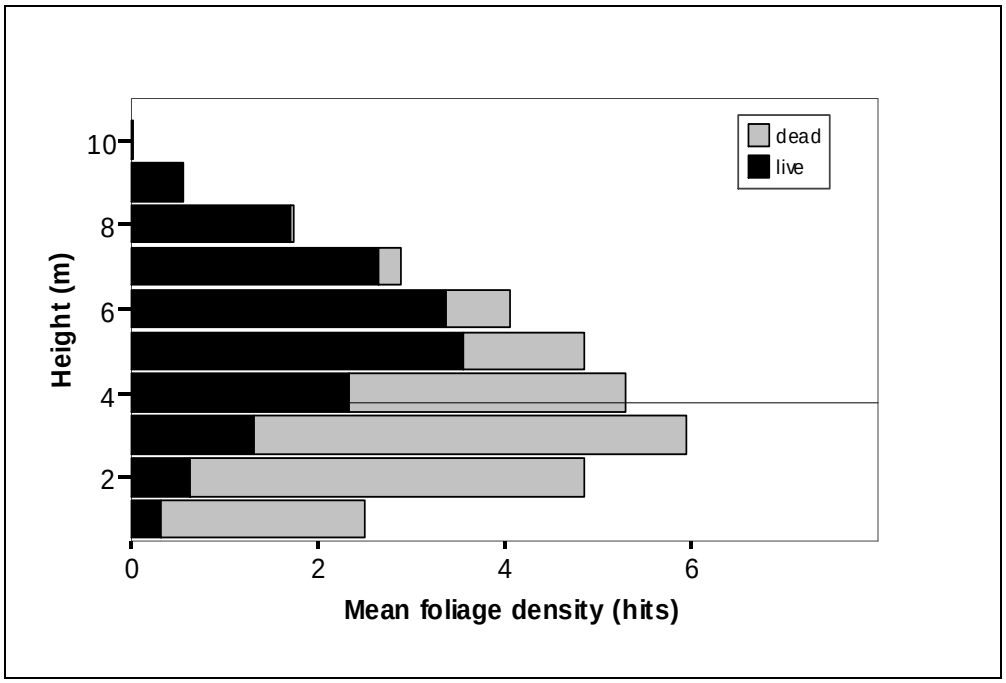

Figure 8.3. Vertical foliage density in areas occupied by flycatchers in at least one year between 2003 and 2009 within the habitat enhancement project area, Topock Marsh, 2009. Horizontal line shows average nest height in the project area, 2003–2008.

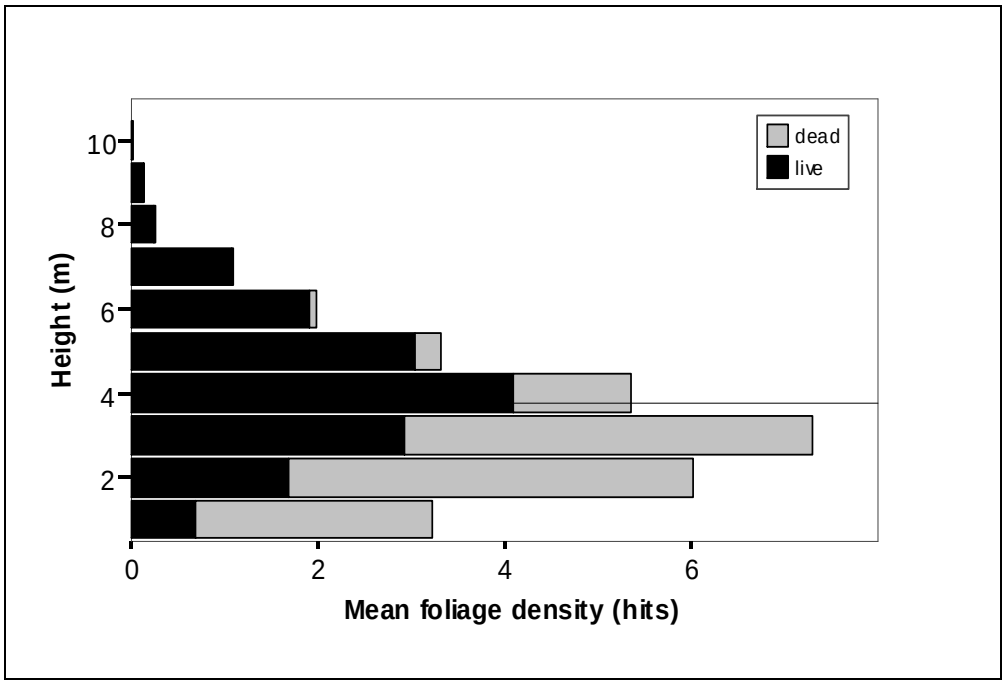

Figure 8.4. Vertical foliage density in areas not occupied by flycatchers between 2003 and 2009 within the habitat enhancement project area, Topock Marsh, 2009. Horizontal line shows average nest height in the project area, 2003–2008.

DISCUSSION

The hydrology, vegetation, and microclimate data collected in 2009 show the pretreatment conditions within the portion of Topock Marsh selected for habitat enhancement via water delivery. Identical methods will be used in 2010 to collect data during the water delivery period, and data from 2010 will be compared to those collected in 2009 to identify any changes in surface hydrology, microclimate, and vegetation.

Chapter 9

MICROCLIMATE AND VEGETATION MONITORING: PAHRANAGAT

INTRODUCTION

From the start of flycatcher monitoring at Pahranagat NWR in 1997 through 2007, occupied flycatcher habitat at Pahranagat North, near the inflow to Upper Pahranagat Lake, has been inundated annually with up to 1 m of water recorded under the vegetation in mid-May. From 2003 to 2007, as much as 100% of the site contained standing water in mid-May, and as much as 95% of the site contained standing water and saturated soil until mid-July. Major structural problems with the levee that impounds the upper lake resulted in the upper lake being drained in early 2008, and the riparian vegetation at the north end of the lake was not flooded during the 2008 and 2009 flycatcher breeding seasons as it had been in previous years.

We collected vegetation and microclimate data within 5–10 m from flycatcher nests (within flycatcher territories) at Pahranagat North in 2005–2007. In 2008, the focus of microclimate and vegetation data collection shifted from comparing conditions in occupied vs. unoccupied habitat to characterizing conditions within flycatcher territories for the purpose of providing data that would inform habitat creation and restoration efforts along the LCR. Data collection at Pahranagat was discontinued in 2008 because the study area is approximately 650 m higher in elevation and experiences a cooler climate than the highest elevation portion of the LCR MSCP study area. In addition, the vegetation at Pahranagat consists primarily of very large and widely spaces trees, and these characteristics are unique to the site and not likely to be replicated in restoration areas. Thus, microclimate and vegetation data were not collected in 2008, the first year Pahranagat North was not inundated, and data collection was not planned for the breeding season of 2009.

In 2009, USFWS retained SWCA to complete microclimate and vegetation measurements at Pahranagat North during the 2009 breeding season and to compare conditions during the inundated period (2005–2007) to those documented in 2009.

METHODS

Microclimate

We deployed HOBO Pro v2 temp/RH data loggers (Onset Computer Corporation, Pocasset, MA) within the area of Pahranagat North that has consistently been occupied by breeding flycatchers. Plot center locations were selected by superimposing a 25 × 25–m grid on an ArcGIS 9.1 software shapefile of the flycatcher breeding area boundary, numbering the grid blocks, selecting blocks by using a random number generator, and using the centroid of each selected block. Plot centers were located in the field by navigating to the given coordinates using a Rino 110 GPS unit. For each HOBO unit we determined the exact height and distance from the tree bole by means of random number sequences as described in Chapter 6. Each logger recorded temperature and humidity at 15-minute intervals and remained in place until the end of the flycatcher breeding season in early August. Soil moisture readings were collected beneath each HOBO logger every two weeks, as described in Chapter 6, from HOBO deployment through HOBO removal.

Vegetation

We completed vegetation measurements in August, after the end of flycatcher nesting activity at Pahranagat North. We used each HOBO as the center for a vegetation plot and collected the same measurements as at the monitoring plots at Topock Marsh (see Chapter 8).

Data Analyses

Microclimate

Soil moisture data were entered into a database as they were collected during the field season. We downloaded data from the HOBO data loggers into databases at the end of the field season and summarized microclimate variables for each HOBO location following the methods presented in Chapter 6. We used one-way ANOVA to compare microclimate measures at within-territory locations from 2005 to 2007 when the site inundated versus 2009 when it was not. Analyses were conducted using SAS® v.9.1.3 (SAS Institute 2003). Data are presented as mean (standard error).

To address whether any observed changes in microclimate could be the result of overall changes in regional climate, we obtained weather station data from the National Climate Data Center (www.ncdc.noaa.gov/oa/ncdc.html) for Caliente, Nevada (Station ID #261358) for 2005–2009. Maximum and minimum daily temperature data were available. We used one-way ANOVA to test whether temperature variables differed between years for the 1 July–15 August period. We used SPSS® Version 16.0 (SPSS Inc.) software for statistical analyses.

Vegetation

Vertical foliage data were restricted to data collected within 1 m of plot center so as to be directly comparable to data collected prior to 2008 and were summarized as described in Chapter 5. Percent native vegetation was calculated as the percent of the foliage hits that consisted of native vegetation. We used the average nest height (3.9 m) recorded at Pahranagat from 2003 to 2009 to delineate below, at, and above nest categories. We used one-way ANOVA to compare vegetation characteristics in 2005–2007 versus 2009. We used SPSS® Version 16.0 (SPSS Inc.) software for statistical analyses.

RESULTS

Microclimate

Twenty-eight HOBO loggers were deployed within flycatcher territories at Pahranagat North in early July. They remained in place until 9 August. Six humidity sensors failed to collect data. These data were compared to data collected at 20 within-territory locations in 2005–2007. We included only those within-territory locations where at least half of the 14 day recording period fell between 2 July and 9 August. Soil moisture was higher during the inundated vs. non-inundated period, as was nocturnal and diurnal vapor pressure (Table 9.1). Temperatures differed between the two periods by mean maximum daily temperature being higher and mean minimum nocturnal temperature being lower during the inundated period. Mean daily maximum and minimum temperatures between 1 July and 15 August at the Caliente weather station did not differ between 2009 and any year from 2005 to 2007.

Table 9.1. Descriptive Statistics and Single Effects for Comparison of Microclimate Characteristics, 2005–2007 versus 2009, Pahranagat North*

Response Variable	2005–2007 (n=20)	2009 (n=28)	Difference	*P*
Soil Moisture				
Mean soil moisture (mV)	826.5 (27.9)	741.7 (24.2)	-84.8	0.03
Temperature				
Mean maximum diurnal temperature (°C)	38.4 (1.0)	33.9 (0.1)	-4.5	<0.01
Mean minimum nocturnal temperature (°C)	15.1 (0.5)	17.1 (0.1)	2.0	<0.01
Mean daily temperature range (°C)	16.3 (0.9)	16.8 (0.1)	0.5	0.54
Humidity				
Mean diurnal vapor pressure (Pa)	1648.0 (60.3)	1385.2 (14.6)	-262.8	<0.01
Mean nocturnal vapor pressure (Pa)	1465.0 (53.0)	1149.3 (13.8)	-315.7	<0.01

* Data are presented as mean (standard error).

Vegetation

We collected vegetation data at 28 locations in 2009. These data were compared to vegetation data collected at 26 within-territory locations in 2005–2007. The only variable that differed between the inundated and non-inundated periods was the percentage of the foliage that consisted of native species (Table 9.2).

DISCUSSION

We anticipated that soil moisture and humidity would be lower in 2009 than when the site was inundated, and these expectations are confirmed by the data. However, without humidity data from a nearby weather station, it is impossible to determine whether lower humidity in 2009 was caused by there being less water under the vegetation or if regional humidity was simply lower in 2009. We had expected that inundated conditions might serve to moderate daily temperatures, but the data showed a higher maximum temperature and lower minimum temperature during the inundated period. These differences could not be accounted for by between-year differences in regional climate, with the Caliente weather station showing no between-year differences for either maximum or minimum temperature.

The difference in percent native foliage between the inundated and non-inundated periods is entirely attributable to the development in 2009 of herbaceous ground cover consisting partially of a non-native *Chenopodium* species and does not reflect any change in the woody vegetation. Vertical foliage density below nest height was greater in 2009 than in 2005–2007; however, the increase was not statistically significant. In each year in 2005–2007, vegetation measurements were collected at the end of the flycatcher breeding season, by which time a dense herbaceous layer consisting primarily of Indian hemp (*Apocynum cannabinum*) had developed throughout the drier parts of the site. Thus, although the herbaceous vegetation in 2009 was present throughout the season rather than developing in mid-summer, these between-year changes are not reflected by vegetation measurements collected in August of each year.

Many of the large trees in the northeastern corner of Pahranagat North have died since 2007 (see Chapter 2), but the area of dead trees comprises a small percentage of the site, and only four of the points sampled

in 2009 were near this area. Thus, any changes in vegetation and corresponding changes in microclimate in the northeastern corner of the site did not appear in the data when points across the site were combined.

Although a comparison of vegetation characteristics from when the site was inundated versus was it was not showed no major changes in woody vegetation, two years may be too short of a time for the vegetation to respond to non-inundated conditions. The trees at Pahranagat North are large and presumably have extensive root systems, and although only a small portion of the site contained surface water during 2008 and 2009, the water table beneath the vegetation throughout the site is presumably high. It may take a longer period of time, or a larger drop in the water table, for any changes in the woody vegetation to be detectable.

Table 9.2. Descriptive Statistics and Single Effects for Comparison of Habitat Characteristics between 2005–2007 and 2009, Pahranagat North *

Parameter	**2005–2007** (n=26)	**2009** (n=28)	**P**
Average canopy height (m)	17.6 (1.1)	18.8 (0.8)	0.388

Chapter 10

MANAGEMENT AND STUDY DESIGN RECOMMENDATIONS

For ease of reference this chapter summarizes all study design and management recommendations discussed in previous chapters.

BROADCAST SURVEYS

Mormon Mesa North and Hedgerow at Mormon Mesa have been completely dry for the last several years, and neither of these sites has supported breeding flycatchers since 2005. We recommend visiting each site at the beginning of the breeding season, when sites are typically wettest, and discontinuing surveys if no surface water or saturated soils are present.

We expanded Virgin River #1 South at Mormon Mesa to explore areas where stream channels were noted on the aerial photograph and during aerial reconnaissance. The channels are incised 1–2 m, and the soils beneath the tamarisk were entirely dry throughout the survey season. We do not recommend continuing surveys in this area in future years because of the dry soil conditions. We recommend surveying only the northern third of the site and the area immediately around the Goodding willow cluster in the southwestern portion of the site because of the short canopy height and dry soil conditions in the remainder of the site.

We completed habitat reconnaissance at several new sites at Muddy River and Topock Marsh. We recommend visiting The Narrows site along the Muddy River at the beginning of the season to assess hydrologic conditions and discontinuing surveys for the season if water is restricted to the active river channel. At Topock Marsh, three sites (Lost Lake Slough #2, Lost Lake Slough #3, and Lost Lake Slough #4) had potential to develop into suitable flycatcher habitat if the vegetation matures. We recommend revisiting these sites in 2010 to assess any changes in the vegetation. The remaining reconnaissance sites (Muddy River Recon, NW Beal Lake, NE Lost Lake, Lost Lake South, and Marina) lacked either the vegetation or hydrologic conditions typical of occupied flycatcher habitat, and we do not recommend revisiting these sites.

We recommend discontinuing surveys at Pulpit Rock in Topock Gorge. The small size of the site, its isolation from other riparian habitat, and its predominantly dry soils make this site unlikely to support resident flycatchers. We also recommend discontinuing surveys in the western portion of Blankenship Bend South because woody vegetation in this portion of the site is widely scattered.

COWBIRD CONTROL

The breeding site at Muddy River is a relatively small stand of tall trees and is bordered to the north by an extensive valley dominated by residential areas and agriculture and containing little riparian vegetation. Muddy River had 33–75% parasitism in four of the five years when flycatchers have been monitored at the study area, and overall nest success was 23%, well below the average of 45% across all study areas in those years. Although the breeding site at Muddy River is not as isolated from surrounding riparian vegetation as the site at Pahranagat, cowbird trapping at Muddy River has the possibility of reducing the parasitism rate and increasing flycatcher nest success, and we recommend that cowbird trapping be instituted at Muddy River.

In addition to cowbird trapping at Muddy River, addling cowbird eggs and removing cowbird young from easily accessible flycatcher nests would likely increase flycatcher nest success and productivity. We do not advise these activities at Pahranagat, which is still part of the five-year post-cowbird-trapping experiment. However, at study areas that were not part of the cowbird trapping experiment (Littlefield, Mormon Mesa, Muddy River, Bill Williams), addling eggs and removing young would not interfere with ongoing experiments and would likely benefit the flycatcher. At Mesquite and Topock, cowbird trapping was shown not to have any effect on parasitism rates and flycatcher nest success, and thus the post-trapping period will not reveal any lingering effects of trapping. Addling cowbird eggs and removing nestlings could thus be implemented at these study areas as well, and we recommend addling cowbird eggs and removing cowbird nestlings from easily accessible flycatcher nests at all sites but Pahranagat.

VEGETATION

The vegetation plot measured at Beal Lake had less canopy closure and far fewer stems than was typical for flycatcher territories in other habitat types, but more extensive sampling would be required to ascertain whether the plot is representative of the site. Because of the uncertainty of whether the site was truly occupied by resident flycatchers and the dissimilarities between the vegetation characteristics measured at Beal Lake and at other flycatcher territories, the vegetation characteristics reported here for cottonwood-mesquite habitat should not be used as a model for flycatcher habitat.

Although the methods for collecting the vegetation data were unchanged among years, observer variation could influence between-year differences in stem counts, vertical foliage counts, and canopy closure. To address observer variation in stem and vertical foliage counts, we calculated the proportion of live stems and live hits in each category and then compared the proportions between the occupied and unoccupied periods. As long as each observer counts live vs. dead stems and, similarly, live vs. dead hits in a consistent manner, this technique accounts for any observer differences in the absolute counts. Reanalysis of the 2003–2007 data incorporating the proportion of live vs. dead vegetation may yield further insight into the vegetation characteristics that contribute to flycatcher occupancy.

HABITAT MONITORING: PARKER TO IMPERIAL DAMS

The relationship of microclimate conditions between the habitat monitoring sites and Topock is well established, and we recommend discontinuing this analysis in future years.

The detection of changes in vegetation as the result of the diversion of water at Parker rather than Imperial Dam is hampered by the complete lack of vegetation measurements prior to the beginning of the diversion in 2002. Vegetation measurements did not commence until 2005, by which time it was possible that some changes in vegetation, particularly in sensitive species such as coyote willow, had already occurred. Other methods, such as analysis of satellite imagery, should be considered to detect any changes in vegetation that might have occurred prior to 2005.

The relationship between groundwater levels and river operations has been established, and the strong influence of daily changes in river discharge on groundwater levels renders the piezometer data unsuitable for tracking changes in evapotranspiration over time. Thus, we recommend removing all the piezometers except the one at Topock Marsh, which may be useful in tracking changes in water levels as part of planned water deliveries to a portion of the flycatcher habitat.

In previous years we correlated piezometer ground water levels and soil moisture measurements and found no strong linear relationship. The strongest relationships were found at sites that had the highest

soil moisture values. This suggests that at sites were soil moisture is low, surface soil moisture content is not influenced by groundwater levels, and soil moisture measurements are unlikely to reflect any changes in water availability caused by changing river levels. We recommend discontinuing soil moisture measurements at Cibola Lake, Havasu NE, Clear Lake, Ferguson Wash, and Gila Confluence North, where soil moisture values are consistently below 600 mV.

Acknowledgements

This project was made possible by the support of many persons, agencies, private landowners, and our dedicated staff and field crew. Work was conducted under the auspices of Federal Fish and Wildlife Threatened and Endangered Species Permit TE028605-1 and Master Banding Permit #23258. Funding was provided by the U.S. Bureau of Reclamation, Boulder City, Nevada (Contract No. GS-10F-0209L). Theresa Olson and Chris Dodge from Reclamation provided background information and guidance, and Mark Santee piloted the helicopter for site tours.

Many thanks to the following national wildlife refuges and personnel for all their assistance and for providing housing: Kevin DesRoberts, Chivia Horton, and Jim Doctor at Pahranagat NWR; John Earl, Jack Allen, and Ty Bennali at Havasu NWR; Dr. Kathleen Blair, Dick Gilbert, and Stan Culling at Bill Williams River NWR; Mike Oldham and Bill Seese at Cibola NWR; and Brenda Zaun and Elaine Johnson at Imperial NWR. Thanks to Keith Day and Pam Wheeler with the Utah Division of Wildlife Resources for their support at Seegmiller Marsh. Also, we would like to thank Cris Tomlinson, Christy Klinger, Ben Conrad, and Keith Brose with Nevada Division of Wildlife for their support at Key Pittman and Overton Wildlife Management Areas.

Thanks to the following agencies and personnel for assistance with obtaining permits: Greg Beatty, Sandy Marquez, Daniel Marquez, Amy Lavoie, Vanessa Martinez, Leilani Takano, Jodi Fraser, and Corey Kallstrom with the U.S. Fish and Wildlife Service; Florence L. Soehnlein and Danny Bystrak with the Federal Bird Banding Laboratory; Melissa Swain with the Arizona Game and Fish Department; Gloria Shaw with Lake Mead National Recreation Area; Luela Roberts, Randi Logsdon, and Esther Burkett with the California Department of Fish and Game; Cris Tomlinson and Julie Meadows with the Nevada Division of Wildlife; Suzanne McMullin with the Utah Division of Wildlife Resources; Stephanie Heinz with the Colorado River Indian Tribe; Tom Denniston with the Bureau of Land Management, St. George; Bill Werner with the Arizona Department of Water Resources; and Bill Dowdle with the Arizona State Lands Department. Robert Bunker, Bill Evans, and Gary Hafen granted access to their properties.

A very special thanks to Eben H. Paxton with the U.S. Geological Survey, Southwest Biological Science Center and Mark K. Sogge with the U.S. Geological Survey, Western Region for support and assistance in all phases of the project. Thanks to Johnny, Mike, and Kathy at Monte Vista Marine, and Brian Dierker and Dr. Steve Carothers for assisting with boating logistics. Jim Christian assisted with ATV logistics.

This project would not be a success without our dedicated staff and field personnel. Many, many thanks to Jessica Maggio and Kimberly MacMillan who went beyond their administrative duties and coordinated housing, permitting, payroll, vehicles, computers, safety and telecommunications and handled all manner of crises with cheerful aplomb. A very special thanks to Glenn Dunno for his GIS talents. Thanks also to Shara Monik, Lisa Jackson, and Kim Wells for administrative and accounting support. And sincere thanks to the 2009 field personnel for hard work, dedication, and sweat.

FIELD DATA FORMS

Willow Flycatcher Survey and Detection Form (revised April, 2004)

Site Name_____ State_____ County _____
USGS Quad Name _____ Elevation _____ feet / meters (circle one)

Is copy of USGS map marked with survey area and WIFL sightings attached (as required)? ☐ *Yes* ☐ *No*

Site Coordinates: Start: N_____ E_____ UTM Datum_____ (NAD27 preferred)
Stop: N_____ E_____ UTM Zone _____

***** Fill in additional site information on back of this page *****

Survey # / Observer(s) (Full Name)	Date (m/d/y) Survey time	Number of Adult WIFLs	Estimated Number of Pairs	Estimated Number of Territories	Nest(s) Found? Y or N	Cowbirds Detected? Y or N	Presence of Livestock, Recent sign, If Yes, Describe Y or N	Comments about this survey (e.g., bird behavior, evidence of pairs or breeding, number of nests, nest contents or number of fledges seen; potential threats)
1_____	Date Start Stop Total hrs_____							
2_____	Date Start Stop Total hrs_____							
3_____	Date Start Stop Total hrs_____							
4_____	Date Start Stop Total hrs_____							
5_____	Date Start Stop Total hrs_____							
Overall Site Summary (Total **resident** WIFLs only) Total survey hrs_____		Adults	Pairs	Territories	Nests	Were any WIFLs color-banded? Yes No If yes, report color combination(s) in the comments section on back of form		

Reporting Individual _____ Date Report Completed _____
US Fish and Wildlife Service Permit #_____ AZ Game and Fish Department (or other state) Permit # _____

Submit original form by August 1st. Retain a copy for your records.

Fill in the following information completely. Submit original form by August 1st. Retain a copy for your records.

Reporting Individual _____ Phone # _____
Affiliation _____ E-mail _____
Site Name_____ Date Report Completed _____

Did you verify that this site name is consistent with that used in previous years? Yes / No (circle one)
If name is different, what name(s) was used in the past? _____
If site was surveyed last year, did you survey the same general area this year? Yes / No If no, summarize in comments below.
Did you survey the same general area during each visit to this site this year? Yes / No If no, summarize in comments below.

Management Authority for Survey Area (circle one): Federal Municipal/County State Tribal Private
Name of Management Entity or Owner (e.g., Tonto National Forest) _____

Length of area surveyed: _____ (specify units, e.g., miles = mi, kilometers = km, meters = m)

Vegetation Characteristics: Overall, are the species in tree/shrub layer at this site comprised predominantly of (check one):

☐ Native broadleaf plants (entirely or almost entirely, includes high-elevation willow)

☐ Mixed native and exotic plants (mostly native)

☐ Mixed native and exotic plants (mostly exotic)

☐ Exotic/introduced plants (entirely or almost entirely)

Identify the 2-3 predominant tree/shrub species: _____

Average height of canopy (Do not put a range): _____ (specify units)

Was surface water or saturated soil present at or adjacent to site? Yes / No (circle one)
Distance from the site to surface water or saturated soil: _____ (specify units)

Did hydrological conditions change significantly among visits (did the site flood or dry out)? Yes / No (circle one)
If yes, describe in comments section below.

Remember to attach a copy of a USGS quad/topographical map (REQUIRED) of the survey area, outlining the survey site and location of WIFL detections. Also include a sketch or aerial photograph showing details of site location, patch shape, survey route in relation to patch, and location of any willow flycatchers or willow flycatcher nests detected. Such sketches or photographs are welcomed, but DO NOT substitute for the required USGS quad map. Please include photos of the interior of the patch, exterior of the patch, and overall site and describe any unique habitat features.

Comments (attach additional sheets if necessary)

SWFL General Site Description

[Complete at least 3 times during season: early (10–25 May), mid-season (10–25 June), and late season (10–25 July)]

General Info

Study Area: _____ **Survey Site:** _____ **Date:** _____

Observer(s): _____ **early**____ **mid**____ **late**____ **other**____

Vegetation

Vegetation at site: >90% native 50–90% native 50–90% exotic >90% exotic

Canopy closure: <25% 25–50% 50–70% 70–90% >90%

Overstory height (m): _____ **Dominant overstory species:** TASP SAGO SAEX POFR Other _____

Understory height (m): _____ **Dominant understory species:** TASP SAGO SAEX PLSE Other _____

Other vegetation types present (e.g., cattail)? Yes No

If yes, type of vegetation: _____ **percentage of site:**_____
type of vegetation: _____ **percentage of site:**_____
type of vegetation: _____ **percentage of site:**_____

Hydrology

% of site inundated: _____

Describe type of surface water (e.g., open marsh, surface water within woody vegetation, stream, etc):
_____

Average depth of surface water:
toes (<5cm) ankles (5-15 cm) calves (15-40 cm) knees (40-60 cm)
thighs (60-80 cm) waist (100 cm) too deep to wade (>100 cm)

% of site with saturated soils (do not include inundated areas in percentage!): _____

% of site with damp soils (do not include inundated or saturated areas): _____

If not inundated or saturated, distance (m) to standing water or saturated soil:_____

How was distance determined? Visually estimated in field Measured in field using GPS
Measured from aerial photograph Other _____

Describe type of nearest surface water: _____

Narrative and Pictorial Description

Does this description cover the entire site? Y N **If not, which portion is described?**_____
_____

On the reverse, sketch and label the locations of the major vegetation types you observed. Delineate marshes, open areas, and other habitat that may be unsuitable for flycatchers. If water was present, show its location.

Give a narrative description of the site, including adjacent habitats:

SIDE 2

SWFL Microclimate at Occupied Territories

Study Area _____ **Survey Site** _____ **LOCATION ID** _____–_____–_____
(Study area) – (Year) – (Territory #)

UTM coordinates: E 0_ _ _ _ _ _ _ **N** _ _ _ _ _ _ _ _ **GPS Accuracy**: _____ m

Date territory first occupied: _____ **Date territory vacated** _____

New Location ID (if this logger was already in the field) _____–_____–_____

Temperature/Relative Humidity (T/RH)

Set-up: Date:_____ Time:_____ Observer(s)_____

Logger 6-digit serial number (e.g., #630863):_____ Was red LED checked at set-up? Y or N

What randomization sequence was used? Sequence #: _____.
Column 1: _____ Column 2: _____ Column 3:_____ Column 4:_____ Column 5: _____

Est. actual height of logger _____ m

Download: Date:_____ Time:_____ Observer(s):_____

Was red LED blinking at download? Y or N Did you check red LED after (re)launch? Y or N

Logger 6-digit serial number (do NOT copy from above; read the number on the logger!):_____

Did any events occur that might have interfered with accuracy of data gathered by this logger (e.g., blown out of tree, etc.)?
No Yes If yes, explain:

Was logger downloaded on-site? Y or N If N, date and time of download: Date: _____ Time: _____

Did you replace the existing logger? Y or N If Y, serial number of new logger: _____

Comments:

Download: Date:_____ Time:_____ Observer(s):_____

Was red LED blinking at download? Y or N Did you check red LED after (re)launch? Y or N

Logger 6-digit serial number (do NOT copy from above; read the number on the logger!):_____

Did any events occur that might have interfered with accuracy of data gathered by this logger (e.g., blown out of tree, etc.)?
No Yes If yes, explain:

Was logger downloaded on-site? Y or N If N, date and time of download: Date: _____ Time: _____

Did you replace the existing logger? Y or N If Y, serial number of new logger: _____

Comments:

Soil Moisture (SM)

Date **soil sample** collected:_____

Soil moisture data collected on the following dates (enter SM data directly into database):

Date: _____ Obs: _____ Date: _____ Obs: _____ Date: _____ Obs: _____

Date: _____ Obs: _____ Date: _____ Obs: _____ Date: _____ Obs: _____

Date: _____ Obs: _____ Date: _____ Obs: _____ Date: _____ Obs: _____

SWFL Microclimate at Old Nests

Study Area _____ **Survey Site** _____ **LOCATION ID** _____–_____–_____
(Study area) – (Year active) – (Nest #)

UTM coordinates: E 0_ _ _ _ _ _ **N** _ _ _ _ _ _ _ **GPS Accuracy**: _____ m

Temperature/Relative Humidity (T/RH)

Set-up: Date:_____ Time:_____ Observer(s)_____

Logger 6-digit serial number (e.g., #630863):_____ Was red LED checked at set-up? Y or N

How certain are you that the logger is hanging from the fork the nest was in? (check one)

_____Nest still visible, certain of location
_____Nest gone, but found nest flag and certain of location
_____Nest gone, no nest flag, but base of nest tree flagged and nest height adequate to determine exact location
_____Nest gone, base of nest tree flagged, certain in right tree but not sure if right fork
_____Nest gone, nest tree not flagged, not certain if in right tree.
_____Other: _____

Est. actual height of logger _____ m

Comments:

Take-down: Date:_____ Time:_____ Observer(s):_____

Logger 6-digit serial number (do NOT copy from above; read the number on the logger!):_____

Did any events occur that might have interfered with accuracy of data gathered by this logger (e.g., blown out of tree, etc.)?
No Yes If yes, explain:

Comments:

Appendix D

ALL WILLOW FLYCATCHERS COLOR-BANDED AND/OR RESIGHTED, 2003–2009

Appendix D. Willow flycatchers banded and/or resighted by SWCA at sites along the Virgin and lower Colorado Rivers in 2003–2009. Table includes individuals banded at sites prior to 2003 (Braden and McKernan, unpubl. data) and recaptured or resighted by SWCA.

PREFACE

This document is one of the deliverables submitted to the U.S. Bureau of Reclamation under contract # GS-10F-0209L to complete Southwestern Willow Flycatcher (*Empidonax traillii extimus*) studies along the lower Colorado River and tributaries in 2009. The document comprises a list of all sites surveyed for willow flycatchers in 2009 and the UTM coordinates (Zone 11, NAD 83) of the centroid of each site (Table 1), along with a compilation of aerial photographs. These aerial photographs include the location, identity, and breeding status of each willow flycatcher detected at study areas where resident flycatchers were detected during 2009 (Figure 1). For additional information regarding methodology and willow flycatcher surveys, demography, and ecology along the lower Colorado River and tributaries in 2009 refer to:

> McLeod, M.A., and T.J. Koronkiewicz. 2010. Southwestern Willow Flycatcher surveys, demography, and ecology along the lower Colorado River and tributaries, 2009. Annual report submitted to U.S. Bureau of Reclamation, Boulder City, NV by SWCA Environmental Consultants, Flagstaff, AZ. 165 pp.

This document is intended for use only by the U.S. Fish and Wildlife Service, the U.S. Geological Survey, Nevada Division of Wildlife, California Department of Fish and Game, and the Arizona Game and Fish Department. Specific locations of Southwestern Willow Flycatcher territories and nests may be considered by some agencies as sensitive information. Therefore, this document is not intended for general distribution. Please contact the U.S. Bureau of Reclamation and U.S. Fish and Wildlife Service for permission to copy and distribute this document.

Color Leg Band Combination Codes:

Color-band codes used on each aerial photograph follow the conventions presented below:

Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band and color-band designations for right and left legs are separated with a colon. **EE** = electric yellow federal band, **PU** = pumpkin federal band, **TQ** = turquoise federal band, **XX** = standard silver federal band, **Bs** = blue federal band, **R** = red, **D** = dark/navy blue, **B** = light blue, **K** = black, **V** = violet, **Z** = gold, **Y** = yellow, **G** = green, **W** = white, **O** = orange, **UB** = unbanded, **(M)** = metal pin striped band.

Nest and Willow Flycatcher Location Codes:

Nest and willow flycatcher location codes on each aerial photograph follow the conventions presented below:

Blue	the approximate use area center for individual willow flycatchers detected at the site for less than 7 days
Yellow	a willow flycatcher nest location
Red	the approximate territory center for a single, territorial willow flycatcher detected at the site for 7 or more days
Green	the approximate territory center for a willow flycatcher pair for which no nesting was confirmed

All locations on the aerial photographs were based on UTM coordinates (Zone 11, NAD 83) obtained in the field in 2009 using a Garmin Rino 110 GPS unit.

PRESENCE/ABSENCE SURVEYS

Field personnel spent 661.2 observer-hours conducting willow flycatcher broadcast surveys at 77 sites along the Virgin and lower Colorado Rivers and tributaries, with sites located in Nevada, California and Arizona (Table 1). Willow flycatcher survey results are summarized and presented below along with site descriptions. The UTM coordinates presented (Table 2) are the centroid of each survey area. All UTM coordinates were obtained in NAD 83 using a Garmin Rino 110 GPS unit. All UTM coordinates in this report are presented in NAD 83 to comply Federal Geographic Data Committee standards.

[2] ND = No willow flycatchers were detected.

[3] Majority of site burned between 2 and 8 July; surveys discontinued.

[4] Named CVCA in previous reports.

[5] Surveys discontinued after 4th survey because of poor quality habitat.

[6] Site completely bulldozed prior to the start of survey season; no surveys completed.

NEVADA

Pahranagat North

Area: 4.6 ha Elevation: 1,026 m

Pahranagat North is a stand of large-diameter Goodding willow (*Salix gooddingii*) at the inflow of Upper Pahranagat Lake. Fremont cottonwood (*Populus fremontii*; hereafter cottonwood) lines the northern, upland edge of the site and extends in narrow stringers around the edge of the lakebed. Canopy height within the patch is 15–18 m, and canopy closure is approximately 70%, similar to that recorded in 2008. Canopy closure from 2003 to 2007 was >90%. Reduced canopy closure in 2008–2009 occurred mostly in the northeastern section of the site, where many of the large trees are now dead or dying. During the survey season, standing water and saturated soils were present only in an inflow channel that runs along the northern side of the site and drains into the lakebed at the southeastern corner of the site. The water channel is vegetated with bulrush (*Schoenoplectus* sp.) where it enters the lakebed. Saturated soils were also present within patches of bulrush that border the southern edges of the site.

We detected 20 breeding willow flycatchers, as well as 1 resident, unpaired male. In addition to resident adults, we detected two individuals for which residency and breeding status could not be confirmed. Areas of Pahranagat North not known to be occupied by willow flycatchers were surveyed five times, totaling 6.1 observer-hours. The site lies immediately adjacent to a cattle pasture, but livestock have access only to the cottonwood stringer on the northwestern corner of the lake, which is separated from the survey site by a fence. Cowbirds were detected during one survey and were detected regularly during nest monitoring activities.

Pahranagat West

Area: 1.5 ha Elevation: 1,026 m

This native site consists of a stringer of cottonwood, one to three trees wide and 20 m in height, on the western edge of Upper Pahranagat Lake. The site has no significant understory vegetation, and canopy closure varies from <50 to 80%. The eastern edge of the site is vegetated with bulrush, which extends into the lakebed to the east. During the survey season, the interior of the site was dry, but surface water was present nearby in the lakebed.

We detected no willow flycatchers. We surveyed the site five times, totaling 3.2 observer-hours. No cowbirds were detected, and there was no sign of livestock use.

Pahranagat MAPS

Area: 2.7 ha Elevation: 1,026 m

Pahranagat MAPS is a stringer of cottonwood on the western edge of the bed of Upper Pahranagat Lake. Canopy height is 15–20 m, and canopy closure is approximately 60%. There is very little woody vegetation in the understory. Cattail (*Typha* sp.) and bulrush line the eastern edge of the tree line and extend into the lakebed; much of this vegetation is dead. The site was dry throughout the survey season, with the nearest water or saturated soil being at least 20 and up to 200 m away in the lakebed.
No willow flycatchers were detected. We surveyed the site five times, totaling 3.5 observer-hours. Cowbird were detected on two surveys, and there was no evidence of livestock use.

Pahranagat South

Area: 2.5 ha Elevation: 1,023 m

Pahranagat South consists of a relatively small stringer of Goodding willow, coyote willow (*Salix exigua*), and cottonwood lining a human-made channel that carries the outflow from Upper Pahranagat Lake. The cottonwoods reach approximately 20 m in height, while the willows are generally less than 10 m. In 2005, we noted that dense coyote willow was increasing on the western side of the site; this area of willow had very sparse canopy in 2006 and 2007, and the coyote willow was almost completely dead by 2008. The site is bordered to the west by an open marsh and to the east by upland scrub. Tamarisk (*Tamarix* spp.) and Russian olive (*Elaeagnus angustifolia*) form a sparse understory. Overall canopy closure at this site is approximately 50%. The channel held water during site visits in May and June but was dry in mid-July.

We detected one willow flycatcher, for which residency and breeding status could not be confirmed, on 22 June after receiving a report from field personnel from an unrelated project that a flycatcher had been detected at the site. The flycatcher was not detected on any of three subsequent territory monitoring visits or on any of the surveys. We surveyed the site five times, totaling 2.8 observer-hours. Cowbirds were detected during two surveys, and no sign of livestock was observed.

Mesquite East

Area: 4.4 ha Elevation: 468 m

This mixed-native site lies on several terraces within the floodplain of the Virgin River in Mesquite, Nevada. Vegetation on the lowest terrace, on the northern edge of the site adjacent to the river, consists of cottonwood and Goodding willow generally less than 10 m in height. The central portion of the site lies on a slightly higher terrace and is vegetated entirely by dense tamarisk 7–8 m in height with canopy closure around 80%. The uppermost terrace is vegetated with Goodding willow and a few cottonwood 18–25 m in height and an understory of dense clumps of coyote willow about 8 m in height. Canopy closure on this terrace varies from 50% in the cottonwood/Goodding willow areas to over 90% in the coyote willow clumps. The western half of the upper terrace burned over the 2004–2005 winter and grew back with thick stands of coyote willow and cottonwood. The site was completely dry throughout the survey season, and the coyote willow was dead or dying.

We detected no willow flycatchers. We surveyed the site five times throughout the flycatcher breeding season, totaling 8.6 observer-hours. Cowbirds were detected on all surveys. Cattle trails and scat were observed on all surveys, and domestic pigs were seen in the site on one occasion.

Mesquite West

Area: 11.5 ha Elevation: 470 m

This mixed-native site lies within the floodplain of the Virgin River in Mesquite, Nevada. Golf courses and housing developments border the site to the north, and the Virgin River borders the site to the south. This large site is primarily a mosaic of cattail and bulrush marshes separated by narrow (40–50 m) strips of dense coyote willow with interspersed tamarisk. The coyote willows are generally 5–6 m in height, and canopy closure varies from 50 to >90%. Hydrology at the site is influenced by irrigation runoff from adjacent golf courses and agriculture. In previous years, the majority of the site was regularly or continuously inundated. At the beginning of the 2009 breeding season, the site was completely dry, and the pond at the western end of the site, which had previously been too deep to wade, had completely dry

soil with deep cracks. Water had previously entered the northeastern corner of the site from a deep trench, but in 2009, what little water was flowing had been diverted down the eastern edge of the site in a trench that had been dug the previous year. During the first site visit in early May, we noted premature leaf abscission in the coyote willows. In the last week of June, we noted surface water within the site for the first time during the season, and it was confined to the eastern portion of the site. This portion of the site received surface water for one day at approximately weekly intervals for the remainder of the breeding season, and the willows appeared to respond with new growth. The rest of the site remained dry, though the cracks in the soil at the western end of the site became shallower, suggesting subsurface water.

We detected 16 breeding willow flycatchers, 1 pair for which no nest was located, and 2 resident, unpaired males. In addition to resident adults, we detected one individual for which residency and breeding status could not be determined. Areas of Mesquite West not known to be occupied by flycatchers were surveyed once at the beginning of the flycatcher breeding season, totaling 2.0 observer-hours. After the initial survey, all areas of the site were covered by territory monitoring, and surveys were discontinued. Cowbirds were detected on the survey and were detected regularly during territory monitoring. Fresh cattle scat was also observed within the site.

Bunker Marsh North

Area: 13.6 ha Elevation: 456 m

This mixed-exotic site lies within the floodplain of the Virgin River near Bunkerville, Nevada, approximately 4 km downstream of Mesquite West. The site is between agricultural fields to the southeast and the Virgin River to the northwest. We explored and surveyed the riparian vegetation along an approximately 1-km reach of the river. The southern end of the site consists of tamarisk 6 m in height with 50–70% canopy closure. This portion of the site is bordered to the north by a small cattail marsh and a strip of 4–5-m-tall Goodding and coyote willow. The tamarisk area was very dry throughout the season and does not represent suitable flycatcher habitat. The willows surrounding the cattail marsh may provide habitat in future years if the area expands and matures. The remainder of the site is a mosaic of 4–6-m-tall tamarisk, scattered Goodding willow, patches of coyote willow 4–5 m in height, and stream channels and marshy areas. Canopy closure ranges from 25 to 90%. One small patch of coyote willow near the center of the site had surface water beneath the woody vegetation; otherwise, the only portions of the site that contained surface water were the marshes, and soils were dry beneath the woody vegetation. The streams and marshes contained surface water through mid-June but were dry in July.

We detected five breeding willow flycatchers and two flycatchers for which residency and breeding status could not be confirmed. Portions of the site not known to be occupied by flycatchers were surveyed five times, totaling 17.0 observer-hours. Cowbirds were detected on four surveys, and cows were observed in the site on multiple occasions.

Mormon Mesa North

Area: 8.2 ha Elevation: 390 m

This mixed-exotic site consists primarily of tamarisk 3–5 m in height with areas of emergent Goodding willow up to 12 m in height and patches of coyote willow. Overall canopy closure is around 50%. The western edge of the site has a 100 x 50 m patch of Goodding willow, 8 m in height, with up to 75% canopy closure and dead cattails in the understory. No standing water or saturated soils were present within the site during the survey season, but surface water was adjacent to the site in May and June in the river channel to the south. The site is perched up to 2 m above the water level. Mormon Mesa North has

been completely dry throughout the breeding seasons of 2004 to present, and no flycatchers have been detected at the site in 2006–2009. Portions of the site, particularly the Goodding willows on the western edge of the site, might provide suitable flycatcher habitat with wetter soil conditions but in recent years have been dry. We recommend visiting this site at the beginning of the survey season to assess hydrologic conditions and discontinuing surveys for the season if the site is completely dry.

We did not detect any flycatchers. We surveyed the site five times, totaling 16.4 observer-hours. Cowbirds were detected on all surveys as was evidence of livestock use.

Hedgerow

Area: 1.1 ha Elevation: 390 m

This mixed-exotic site is east of Mormon Mesa North, on the eastern side of the Virgin River. The site consists of a continuous understory of tamarisk 4–5 m in height with scattered emergent Goodding willow up to 12 m in height. Many of the willows have dead branches. The site is surrounded by tamarisk and arrowweed (*Pluchea sericea*) 2–3 m in height. Canopy closure at the site varies from about 50% on the edges of the site up to 80% in the denser areas. Soils within the site were dry throughout the survey season. No flycatchers have been detected in Hedgerow since we began surveys in 2005, and the site has been completely dry in each year. We recommend visiting this site at the beginning of the survey season to assess hydrologic conditions and discontinuing surveys for the season if the site is completely dry.
We did not detect any flycatchers. We surveyed the site five times, totaling 2.3 observer-hours. Cowbirds were detected on three visits.

Mormon Mesa South

North half: Area: 8.9 ha Elevation: 385 m
South half: Area: 3.4 ha Elevation: 385 m

This mixed-exotic site was split into two contiguous areas to facilitate tracking of survey activity. Habitat evaluation at the beginning of the survey season revealed that the Goodding willow in the western third of the area that had been surveyed in previous years was entirely dead, and we discontinued surveys in this portion of the site. The remainder of the site has scattered Goodding willow up to 20 m in height and a patchy understory of tamarisk 4–7 m in height. Clumps of coyote willow are present on the eastern edge of the site, and dead cattail is present in the understory in this area. Canopy closure is widely variable, ranging from >90% in tamarisk thickets to <50% in openings. There was no surface water within the site, but damp soils were noted on the eastern edge of the site in May and June. The presence of dead cattails and deadfall suggest that this site was formerly considerably wetter, and portions of the site still have the structure to provide potential flycatcher habitat with wetter soil conditions.

No willow flycatchers were detected. We surveyed the northern and southern halves of the site five times each, totaling 12.3 and 7.5 observer-hours, respectively. Cowbirds were detected on all but one survey.

Virgin River #1

North half: Area: 12.0 ha Elevation: 380 m
South half: Area: 34.7 ha Elevation: 380 m

Virgin River #1 was also divided into two areas, Virgin River #1 North and Virgin River #1 South, to facilitate streamlining of field logistics. Habitat assessment in Virgin River #1 North at the beginning of the survey season revealed most of the Goodding willow in the northwestern finger of the area that had

been surveyed in 2008 were dead, and surveys in this area were discontinued. The southeastern corner of the formerly surveyed Virgin River #1 North consists of clumps of tamarisk 4–6 m in height, dry soil, and 60% canopy closure; surveys were discontinued in this area as well. The remainder of Virgin River #1 North is primarily tamarisk 4–6 m in height, with areas of emergent Goodding willow and patches of coyote willow in the central and southwestern portions of the site. Canopy closure throughout the site is 50–70%. Surface water and mud were present in May in channels running north to south through the center of the site, and the southwestern corner of the site also contained surface water in May and June.

We detected three breeding flycatchers and one individual for which residency and breeding status could not be confirmed in the southwestern corner of Virgin River #1 North. Areas of this site not known to be occupied by flycatchers were surveyed five times, totaling 23.5 observer-hours. Cowbirds were detected on all but one survey.

We expanded Virgin River #1 South approximately 600 m to the south and east to explore areas where stream channels were noted on the aerial photograph and during aerial reconnaissance. This new area consists of monotypic tamarisk up to 5 m in height with 70–90% canopy closure. Some of the stream channels contained surface water in May and June and damp soil in July. The channels are incised 1–2 m, and soils beneath the tamarisk were entirely dry throughout the survey season. We do not recommend continuing surveys in this area in future years. The northwestern portion of the site has coyote and Goodding willows interspersed with tamarisk 4–5 m in height. Goodding and coyote willows average 8 and 5 m in height, respectively. This portion of the site contained surface water throughout the survey season and has open, marshy areas. Canopy closure varies from >90% in areas of dense willow and tamarisk to 25% in marshy openings. The middle portion of the site consists of sparser tamarisk 4 m in height with dry, open areas, and the southwestern part of the site consists primarily of tamarisk 3–5 m in height and canopy closure from 60 to 80%. The southwestern part of the site also contains one cluster of emergent Goodding willow 10 m in height with dead coyote willow in the understory, and tamarisk in this area is up to 8 m in height. Soils in this area were damp, but no surface water was noted. For future years we recommend surveying only the northern third of the site and the area immediately around the Goodding willow cluster in the southwestern portion of the site.

We detected 19 breeding willow flycatchers and 4 unpaired, resident males in the northwestern portion of Virgin River #1 South. We detected six additional willow flycatchers for which residency and breeding status could not be confirmed. Areas of the site not known to be occupied by willow flycatchers were surveyed five times, totaling 29.5 observer-hours. Cowbirds were observed on all surveys.

Virgin River #2

Area: 36.9 ha Elevation: 380 m

This site is primarily a monotypic stand of tamarisk 6 m in height with 70–90% canopy closure. Widely scattered emergent Goodding willow up to 10 m in height are present in the northern half of the site. A clump of Goodding willow occurs halfway down the eastern edge of the site, and scattered willows extend to the southern end of the site. The tamarisk in the willow area was dry and brittle, and a greater proportion of mid-sized tamarisk stems were dead than had been in previous years (see Chapter 5). The site contained no surface water during the breeding season, though portions of the site contained damp soils. The Virgin River, on the eastern edge of the site, had surface water throughout the season. No flycatchers have been detected in the northern half of the site from 2003 to present, and we recommend discontinuing surveys in this area.

We detected one willow flycatcher for which residency could not be confirmed. We surveyed the site five times, totaling 51.5 observer-hours. Cowbirds were observed on all surveys.

Overton WMA Pond

Area: 0.7 ha Elevation: 378 m

This site consists of a patch of mixed-native vegetation approximately 150 m long and 150 m wide at the north end of Overton WMA just south of Honeybee Reservoir. The dominant vegetation consists of 10-m-tall Goodding willow with a sparse 5-m-tall tamarisk understory. Cattail and sedges (*Carex* sp.) are also present on the edges of the site. Canopy closure is variable, ranging up to 90%. A small stream channel runs through the site, and it held surface water throughout the season.

We detected no willow flycatchers. We surveyed the site five times for a total of 3.4 observer-hours. Cowbirds were detected two visits, and no sign of livestock use was observed.

Overton WMA

Area: 14.9 ha Elevation: 378 m

This site consists of a 150-m-wide strip of riparian vegetation spanning both sides of the Muddy River. The site is bordered to the southwest by open agricultural fields and to the northeast by sparser areas of riparian vegetation. The site flooded heavily during the 2004–2005 winter, but vegetation at the site was relatively unchanged. The northern portion of the site is dominated by very dense tamarisk up to 7 m in height with canopy closure of 70–90%. The southern portion of the site consists primarily of a stand of Goodding willow 10–12 m in height with an understory of tamarisk and cattail and canopy closure up to 90%. Flowing water was present in the channel of the Muddy River throughout the survey season, and extensive beaver activity resulted in the southern portion of the site being flooded with approximately 30 cm of water through mid-July, at which time water was restricted to channels and the area that had previously been flooded was only muddy. Beavers have felled swaths of Goodding willow in the southern portion of the site, resulting in gaps in the canopy. Approximately 0.3 ha of the southern portion of the site was bulldozed in 2005 as part of Overton WMA efforts to repair flood damage to their water control system. Two stretches of the channel of the Muddy River within the site were dredged with heavy equipment over the 2007–2008 winter, resulting in a cleared swath 10–15 m wide on the western bank of the river.

We located 11 breeding willow flycatchers and 2 unpaired, resident males. We also detected four flycatchers for which residency could not be confirmed. Portions of the site not known to be occupied by flycatchers were surveyed five times, totaling 21.9 observer-hours. We observed no signs of livestock but detected cowbirds on all surveys.

AR063747

ARIZONA

Littlefield Poles

Area: 4.7 ha Elevation: 565 m

Littlefield Poles consists of primarily native vegetation located on Beaver Dam Wash, immediately upstream and downstream of the Highway 91 Bridge. Vegetation upstream of the bridge consists of a scattered overstory of cottonwood averaging 25 m in height. Cottonwood and Goodding willow averaging 10 m in height are present below the overstory but do not form a continuous canopy. Lower strata vegetation approximately 6 m in height consists of coyote willow, tamarisk, and some Russian olive. Dense stands of coyote willow border the southern edge of the patch, along the stream. Downstream of the bridge, young stringers of Goodding and coyote willow reach 5 m in height and form linear patches 10–15 m wide on the edges of multiple stream channels. Larger Goodding willow is present along the southwestern edge of the site on the edge of a golf course, and a dense patch of Goodding willow is present on the northern edge of the downstream end of the site. The downstream end of the site borders a cattail marsh. Canopy closure in the densest areas of Goodding and coyote willow is >90%, though overall canopy closure ranges from 50 to 70%. Surface water was present in stream channels and in the cattail marsh throughout the survey season.

We detected three breeding willow flycatchers; one resident, unpaired male; and one willow flycatcher for which residency could not be confirmed. Portions of the site not known to be occupied by flycatchers were surveyed five times, totaling 14.5 observer-hours. Cowbirds were detected on all surveys, and cattle scat and trails were observed in the site.

Topock Marsh, Arizona

Topock Marsh lies within Havasu NWR and encompasses over 3,000 ha of open water, cattail and bulrush marsh, and riparian vegetation. A large expanse (over 2,000 ha) of riparian vegetation occupies the Colorado River floodplain between the Colorado River on the western edge of the floodplain and the open water of Topock Marsh on the eastern edge of the floodplain. The vegetation is primarily monotypic tamarisk with isolated patches of tall Goodding willow. Seasonally wet, low-lying areas are interspersed throughout the riparian area. Feral pigs are present throughout the Topock study area, and evidence of pigs was observed in all survey sites.

Pipes #1

Area: 5.2 ha Elevation: 140 m

This exotic site is bordered to the east by the refuge road and consists primarily of monotypic tamarisk 5–7 m in height. Arrowweed occurs in dense patches within 50 m of the refuge road. The tamarisk is densest within 100 m of the refuge road and becomes more open toward the western edge of the site. The northern edge of the site has the tallest canopy, and there is relatively little deadfall in this area compared to the rest of the site. The central and southern portions of the site have many dead stems and clusters of fallen trees. Canopy closure is 70–90%. The site contained no standing water during the survey season but did contain damp soils along the southern edge of the site throughout the season.

AR063748

We detected one willow flycatcher, for which residency was not confirmed, on 15 May. Three subsequent territory monitoring visits and four subsequent surveys failed to detect the flycatcher again. We surveyed the site five times, totaling 9.0 observer-hours. Cowbirds were detected on all surveys.

Pipes #3

Area: 5.7 ha Elevation: 140 m

This site is bordered to the east by the refuge road. Arrowweed occurs in dense patches within 50 m of the road. Most of the site is vegetated by tamarisk 4–6 m in height. The southeastern portion of the site has a few emergent Goodding willow up to 15 m in height and open, marshy areas. Canopy closure generally exceeds 70%. In May, the portion of the site with Goodding willow and marshes was inundated with up to 10 cm of water, and the central portion of the site had water up to 30 cm in depth beneath the tamarisk. The site progressively dried out through the season but still contained damp soils and standing water in pig wallows in July.

We detected one territorial male flycatcher in Pipes #3. We also detected a second flycatcher at the site on 9 and 13 June. The second flycatcher was interacting with the territorial male and was possibly a female. The second flycatcher was not detected on any of nine territory monitoring visits after 13 June, however. Portions of Pipes #3 not known to be occupied by flycatchers were surveyed five times, totaling 5.3 observer-hours. Cowbirds were detected on three surveys.

The Wallows

Area: 0.4 ha Elevation: 140 m

The Wallows is primarily vegetated by tamarisk 5–6 m in height with emergent Goodding willow on the western side of the site. The northwestern edge of the site borders an open cattail marsh. Overall canopy closure ranges from 50% in the marshy area to 90% in the tamarisk. Half the site was inundated in May, but by mid-June water was present only in intermittent puddles in the marsh, and by mid-July the only remaining surface water was in pig wallows.

We detected two breeding flycatchers and detected another individual on a single occasion on 15 May. Portions of the site not known to be occupied were surveyed 5 times, totaling 5.0 hours. Cowbirds were detected on four surveys.

PC6-1

Area: 4.8 ha Elevation: 140 m

PC6-1 is a mixed-exotic site consisting primarily of tamarisk 6–7 m in height, with a few patches of arrowweed and cattails present in the understory. A scattered overstory of Goodding willow approximately 10–15 m in height is present in the southwestern corner of the site. Arrowweed 1–2 m in height is present under the willow. A portion of the site within approximately 50 m of the refuge road contains thick stands of arrowweed. Canopy closure in the interior of the site is approximately 90%, while canopy closure on the periphery of the site near the refuge road is approximately 50%. Approximately 60% of PC6-1 contained standing water and saturated soils in May. By mid-June only small puddles remained, and <1% of the site had saturated soil in July.

We detected one willow flycatcher between 2 and 6 June. The site was surveyed five times, totaling 11.0 observer-hours. Cowbirds were detected on three surveys.

Pig Hole

Area: 2.4 ha Elevation: 140 m

Pig Hole consists of monotypic tamarisk 6–7 m in height, with canopy closure ranging from 70 to 90%. The northern edge of the site has smaller-diameter tamarisk, with many wispy branches, than the remainder of the site. Approximately 5% of the site consists of dense patches of arrowweed. Approximately 15% of the site had standing water in May, and another 15% of the site had saturated soils. The standing water had disappeared and only 10% of the site contained saturated soils by mid-June, and by mid-July there was no saturated soil in Pig Hole.

No willow flycatchers were detected. The site was surveyed five times, totaling 5.3 observer-hours. Cowbirds were detected on two surveys.

In Between

Area: 7.7 ha Elevation: 140 m

In Between consists of monotypic tamarisk 6–8 m in height. The lowest 3 m of the stand generally lacks foliage, resulting in a relatively open understory. Canopy closure is 70–90%, and the western edge of the site borders a marsh. Approximately 25% of the site was inundated in May, but no standing water remained by mid-July.

We detected no flycatchers in In Between. We surveyed the site five times, totaling 9.8 observer-hours. Cowbirds were observed on all surveys.

800M

Area: 6.1 ha Elevation: 140 m

800M adjoins the western edge of In Between, and the eastern half of the site consists of a cattail and bulrush marsh with clumps of tamarisk 5–7 m in height and scattered, emergent Goodding willow. The remainder of the site is vegetated by tamarisk 4–7 m in height. Canopy closure in the tamarisk is generally >90%, while canopy closure in the marsh is around 50%. The far southern end of the site, within 50 m of the refuge road, consists of very dry tamarisk 3-5 m in height and is not suitable flycatcher habitat. Approximately 40% of the site was inundated in May, but surface water was restricted to a few puddles within the marsh by mid-June.

We detected one resident male flycatcher. Portions of the site not known to be occupied were surveyed five times, totaling 6.5 observer-hours. Cowbirds were observed on all surveys.

Pierced Egg

Area: 6.7 ha Elevation: 140 m

This mixed-exotic site borders the western edge of 800M and consists of dense tamarisk 7 m in height, with a scattered overstory of Goodding willow 15 m in height. Areas with willows tend to have a more open understory and contain patches of cattail and bulrush. Overall canopy closure is approximately 80%. Approximately 40% of the site was inundated in May, but by mid-June, the only remaining water was in deep pig wallows.

We located two resident male flycatchers and three additional flycatchers for which residency could not be confirmed. Two of the additional flycatchers were detected on 16 and 19 June, one in each of the occupied territories, and were suspected to be females. They were not detected on any of eight territory monitoring visits after 19 June. The third flycatcher for which occupancy could not be determined was detected along the refuge road on 8 June. We surveyed portions of the site not known to be occupied by flycatchers five times for a total of 8.5 observer-hours. Cowbirds were observed on all surveys.

Swine Paradise

Area: 1.0 ha Elevation: 140 m

This mixed-exotic site borders the open water of Topock Marsh. Vegetation at the site consists of tamarisk 6–8 m in height and scattered, emergent Goodding willow up to 15 m in height, with patches of coyote willow. Overall canopy closure is approximately 80%. The interior of the site was dry throughout the survey season, but standing water and saturated soils persisted throughout the season in the marsh on the eastern edge of the site.

No willow flycatchers were detected. We surveyed the site five times, totaling 4.0 observer-hours. We detected cowbirds on four visits.

Barbed Wire

Area: 2.4 ha Elevation: 140 m

One large, emergent Goodding willow occurs at the site; otherwise, the site is vegetated by tamarisk 6–10 m in height and of varying density. The northeastern portion of the site contains taller stems, less dead wood in the understory, and fewer large canopy openings than the southwestern portion of the site. Canopy closure is approximately 90%. Standing water was present in pig wallows in May and June.
We detected no willow flycatchers. We surveyed the site five times, totaling 7.3 observer-hours. Cowbirds were detected on three visits.

Platform

Area: 1.3 ha Elevation: 140 m

This site forms a narrow strip of vegetation between the main refuge road and the open marsh. Vegetation at the site consists of tamarisk 7 m in height with a few isolated, emergent Goodding willow. Overall canopy closure is approximately 90%. Bulrush and cattail line the eastern edge of the site adjacent to the marsh. The interior of the site was dry in June and July.

No willow flycatchers were detected. We surveyed the site five times, totaling 3.5 observer-hours. Cowbirds were detected on three visits.

250M

Area: 1.9 ha Elevation: 140 m

This site lies between the main refuge road and the open marsh. Vegetation composition and structure varies with distance from the marsh. Closest to the refuge road the site is dominated by mesquite trees (*Prosopis* sp.) with an understory of arrowweed. The center of the site is dominated by tamarisk approximately 7 m in height. Closest to the marsh, the site contains patches of coyote willow and one

emergent Goodding willow approximately 12 m in height. Canopy closure within the site ranges from 70 to 90%. The patch of coyote willow on the northern border of the site was inundated in May and June but dry in July. The remainder of the site was dry throughout the survey season.

We detected three willow flycatchers; one on 21 May, one on 3–7 Jun, and one on 25 Jun. Residency could not be confirmed for any of these individuals. The site was surveyed five times, totaling 5.3 observer-hours. Cowbirds were detected on all surveys.

Hell Bird and Glory Hole

Hell Bird: Area: 3.3 ha Elevation: 140 m
Glory Hole: Area: 5.0 ha Elevation: 140 m

These contiguous mixed-exotic sites are located on an island separated from the main riparian area by a narrow, deep channel. Vegetation composition and structure are highly variable, with the survey areas vegetated primarily by a mosaic of tamarisk 6–8 m in height and Goodding willow 15 m in height. Canopy closure ranges from 50 to 90%. The survey areas are bordered on the west by a sand dune and on other sides by dense bulrush. Large swampy areas vegetated by cattail and bulrush are interspersed throughout the survey areas. The proportion of Hell Bird covered by surface water declined from 70% in May to 10% in mid-June and 0% in mid-July. Water levels in Glory Hole declined similarly throughout the season, with 30% of the site being inundated with up to 70 cm of water in early June and only damp soils remaining by mid-July.

We detected two unpaired, resident male flycatchers in Hell Bird and four unpaired, resident males in Glory Hole. In Glory Hole, we detected three additional flycatchers for which residency was not confirmed. Hell Bird was surveyed five times, totaling 10.0 observer-hours. Portions of Glory Hole not known to be occupied by flycatchers were surveyed five times, totaling 1.9 observer-hours. Cowbirds were detected on all surveys in Hell Bird and two surveys in Glory Hole.

Beal Lake

Area: 13.9 ha Elevation: 140 m

This mixed-native restoration site consists of a mosaic of cottonwood, Goodding willow, coyote willow, and arrowweed, with some tamarisk and mesquite scattered throughout the site. Canopy height is highly variable and averages approximately 5 m; canopy closure is sparse, averaging 35%. The amount of standing water and saturated soil is highly variable because it is flood irrigated. Sandy soil at the site allows the water to drain rapidly after irrigation, and the site was dry on all survey visits.

We detected one willow flycatcher on 15–23 May and another on 3 Jun. A third flycatcher was caught in a mist net at Reclamation's MAPS station on 15 May; this flycatcher was later confirmed to be the breeding male in The Wallows. We surveyed this site five times, totaling 9.3 observer-hours. Cowbirds were detected on four surveys.

Lost Slough

Area: 1.5 ha Elevation: 140 m

Lost Slough is located approximately 4 km south of Glory Hole and Hell Bird. This mixed-exotic site runs northeast to southwest for approximately 250 m, and measures 100 m wide at the broadest point. There is a marshy area in the center of the site; a small area of bulrush is present in the marsh, along with

AR063752

stands of coyote willow 6 m in height. Vegetation around the marsh is composed mainly of 6- to 8-m-tall tamarisk with a few emergent Goodding willow and scattered screwbean mesquite (*Prosopis pubescens*). Arrowweed up to 2 m in height makes up the understory vegetation. Canopy closure at the site is variable, with open areas toward the edges of the site and over 70% closure in areas with thick vegetation. Hydrologic conditions at the site were not assessed in May. In mid-June, the marshy area was inundated, and by mid-July small pools remained in the marsh.

We did not detect any willow flycatchers. We surveyed Lost Slough five times, totaling 5.0 observer-hours. Cowbirds were detected during one survey.

Lost Pond

Area: 1.2 ha Elevation: 140 m

This mixed-exotic site is located approximately 700 m southeast of Lost Slough. The site is approximately 200 m long and 125 m wide, with a small pond at the southern edge of the site and a marshy area at the northern end of the site. The edges of the pond are vegetated with a 30-m-wide border of cattail, bulrush, and sedges. Vegetation within the site consists primarily of tamarisk 4 to 7 m in height with canopy closure approximately 90%. The area surrounding the site consists of arrowweed, 3-m-tall tamarisk, and screwbean mesquite. In May, 75% of the site was inundated, but by mid-June water remained only in the pond and marshy areas adjacent to the site.

No willow flycatchers were detected. We surveyed the site five times, totaling 6.3 observer-hours. Cowbirds were detected during one survey.

Lost Lake

Area: 3.3 ha Elevation: 140 m

This site lies approximately 850 m southeast of Lost Pond. It is a narrow (<100-m-wide) strip of riparian vegetation separated from the Colorado River to the southwest by a low ridge of barren sand dunes and bordered to the northeast by marshy areas. The northern edge of the site consists of an overstory of planted cottonwoods 10–15 m in height, with an understory of tamarisk 5 m in height, on the edge of a cattail marsh. South of the cottonwoods, the site is primarily tamarisk, 5–8 m in height, with small openings vegetated by arrowweed. In previous years, the southeastern end of the site was dominated by dense stands of coyote willow. These willows are now all dead, dramatically reducing the suitability of the site for breeding flycatchers. Overall canopy closure is approximately 80%. The only surface water or saturated soil at Lost Lake was immediately adjacent to the marsh on the northern edge of the site; the interior of the site was dry throughout the survey season.

We detected one willow flycatcher on 29 May. The flycatcher responded to broadcasts but did not vocalize spontaneously. The flycatcher was not detected on three subsequent territory monitoring visits or any of the four subsequent surveys. We surveyed the site five times, totaling 4.5 observer-hours. Cowbirds were detected on four visits.

Pulpit Rock

Area: 2.1 ha Elevation: 140 m

This mixed-exotic site lies where an unnamed wash enters the Colorado River from the Mohave Mountains. The northwestern edge of the site is vegetated by cattails and borders a backwater, and the

upland edge is vegetated by arrowweed, honey mesquite (*Prosopis glandulosa*), and ironwood (*Olneya tesota*). Vegetation within the site consists primarily of tamarisk up to 5 m in height, with small patches of coyote willow near the marsh edge. Canopy closure is around 80% near the marsh but only 30% at the upland edges of the site. Hydrologic conditions at the marsh interface were not assessed, but the majority of site appeared to by dry.

No willow flycatchers were detected. We surveyed the site five times, for a total of 2.5 observer-hours. Cowbirds were detected on one survey, and we observed burro tracks and trails around the site. One migrant willow flycatcher has been detected at this site since we began surveying it in 2003. The small size of the site, its isolation from other riparian habitat, and its predominantly dry soils make this site unlikely to support resident flycatchers, and we recommend discontinuing surveys at this site.

Picture Rock

Area: 4.6 ha Elevation: 138 m

This mixed-exotic site consists of two patches of riparian vegetation where an unnamed wash enters the Colorado River from the west. Vegetation within the site consists primarily of tamarisk 5–6 m in height, scattered Goodding willow 12 m in height, and one small patch of coyote willow. Bulrush and cattail are present on the edge of the site along the river, and the upland edges of the site contain arrowweed, mesquite, and paloverde (*Parkinsonia* sp.). Canopy closure within the tamarisk is 70–90%. Surface water was confined to the edge of the site adjacent to the marsh and did not extend under the woody vegetation.

No willow flycatchers were detected. We surveyed the site five times, for a total of 7.3 observer-hours. Cowbirds were detected on two surveys, and burro tracks and trails were observed around the site.

Blankenship Bend North

Area: 26.7 ha Elevation: 138 m

Blankenship Bend contains riparian and marsh vegetation along the eastern bank of the Colorado River adjacent to the Blankenship Valley. The eastern edge of Blankenship Bend North consists of a 100-m-wide strip of vegetation that grades from mesquite 7 m in height at the upland edge to tamarisk and then to a narrow strip of coyote willow 5 m in height. The coyote willow borders a bulrush marsh, and the western edge of the marsh is also vegetated by a narrow (5–10-m-wide) strip of coyote willow as well as several emergent Goodding willow 12 m in height. The remainder of Blankenship Bend North extends for another 400 m to the west until it reaches the open water of the Colorado River. This portion of the site consists of a mosaic of marshes, tamarisk, coyote willow, arrowweed, and mesquite. Vegetation height generally does not exceed 5 m, and canopy closure within the woody vegetation varies between 60 and 80%.

We detected no flycatchers at Blankenship Bend North. We surveyed the site five times, totaling 18.3 observer-hours. We detected cowbirds on all surveys, and evidence of feral pigs and burros was observed.

Blankenship Bend South

Area: 25.9 ha Elevation: 138 m

The eastern edge of Blankenship Bend South consists of a 100-m-wide strip of tamarisk up to 6 m in height with clumps of emergent Goodding willow up to 12 m in height. This strip of vegetation is bordered to the east by dry, upland vegetation and to the west by bulrush marsh and open water. Between this strip of vegetation and the river, approximately 600 m to the west, the site consists primarily of bulrush marsh with widely scattered clumps of tamarisk up to 5 m in height. Canopy closure is approximately 80% in the eastern portion of the site and less than 50% in the remainder of the site. Because woody vegetation in the western portion of the site is widely scattered, we recommend discontinuing surveys in this portion of the site in future years. The site contained standing water throughout the survey season, with up to 80% of the site inundated.

We detected no flycatchers at Blankenship Bend South. We surveyed the site five times, totaling 14.3 observer-hours. We detected cowbirds on all surveys but did not observe signs of livestock.

Bill Williams River National Wildlife Refuge, Arizona

The Bill Williams River NWR contains the last expanse of native cottonwood-willow forest in the LCR region. The refuge encompasses over 2,500 ha along the Bill Williams River upstream from its mouth at Lake Havasu and contains a mixture of native forest, stands of monotypic tamarisk, beaver ponds, and cattail marsh. Survey sites within Bill Williams are listed below from west to east, moving progressively farther upstream. We did not observe evidence of livestock use at any of the Bill Williams sites.
In addition to the regularly scheduled surveys, we revisited one site located in previous years that was determined to be potentially suitable flycatcher habitat. Results of this habitat evaluation are presented following the survey results.

Burn Edge

Area: 3.7 ha Elevation: 140 m

Burn Edge is near the northern edge of the Bill Williams riparian corridor, on the eastern edge of an area that burned in 2006. A cattail marsh with Goodding willow and cottonwood 15 m in height runs east-west through the center of the site. This portion of the site also has clumps of tamarisk up to 6 m in height. Canopy closure in the marshy area varies from around 60% at the eastern end to 25% at the western end. The area on either side of the marsh consists of tamarisk 6 m in height with up to 90% canopy closure. The entire marshy area was inundated in May to a depth up to 40 cm. Intermittent pools were present in mid-June, and by late July only two puddles remained.

No willow flycatchers were detected at Burn Edge. We surveyed the site five times, totaling 5.8 observer-hours. Cowbirds were detected on four visits.

Bill Williams Site #4 and Site #3

Site #4: Area: 9.9 ha Elevation: 140 m
Site #3: Area: 9.5 ha Elevation: 140 m

These two sites are contiguous and together are known as Mosquito Flats. Vegetation is mixed-native, with an overstory of Goodding willow 15–20 m in height and patches of monotypic tamarisk up to 8 m in height. Patches of coyote willow are also present. Canopy closure is variable and overall is approximately 50%. Stands of cattails and marshy areas occupy approximately 10% of Site #3. The understory in some areas is very open, and the ground in these areas is covered with herbaceous vegetation. Many large willows and cottonwoods have fallen over the past several years, leaving large gaps in the canopy and creating patches of thick, dead, fallen woody vegetation. Mosquito Flats had a

network of small, flowing streams in May, but these had dried to damp soil by July. The marshes in Site #3 were dry by July, and the only surface water remaining in Mosquito Flats was in the northwestern corner of Site #4 in a deep backwater channel.

We detected two resident, male flycatchers in Site #4 and detected two additional flycatchers for which residency was not confirmed. One of these was observed on 16–18 June in one of the occupied territories and was suspected to be a female, though it was not observed on any of five subsequent territory monitoring visits. Eight breeding flycatchers were detected in Site #3. Portions of the sites not known to be occupied by flycatchers were visited five times, totaling 14.3 observer-hours at Site #4 and 7.3 observer-hours at Site #3. Cowbirds were detected on all surveys of Mosquito Flats.

Last Gasp

Area: 2.1 ha Elevation: 140 m

Last Gasp is a narrow, mixed-native site along a channel on the northern edge of the Bill Williams riparian area, approximately 250 m east of Burn Edge. Vegetation within the site consists of a broken overstory of cottonwood and Goodding willow 15–20 m in height and a tamarisk understory 5–7 m in height. The bottom of the channel is 1–2 m below the surrounding ground surface. Canopy closure varies from 50% in the channel to 80–90% in the surrounding tamarisk. The channel contained intermittent pools in May. One pool remained in mid-June and by mid-July no surface water was present. No willow flycatchers were detected at Last Gasp. We surveyed the site five times, totaling 7.0 observer-hours. Cowbirds were detected on all visits.

Bill Williams Site #5

Area: 6.8 ha Elevation: 143 m

Site #5 is located on the eastern edge of the Bill Williams River floodplain and is bordered to the northeast by steep cliffs and to the west by a dry river channel. The survey site was expanded in 2008 approximately 350 m upstream, and in 2009 we ceased surveying the most downstream 250 m of the site. The discontinued area consists of deep pools surrounded by completely dry, patchy tamarisk 4 m in height and does not resemble occupied flycatcher habitat. Vegetation in the site is mixed-native, with Goodding willow and cottonwood 15–20 m in height in the overstory. The understory consists of tamarisk 7 m in height as well as some young Goodding willow and cottonwood. Ground cover in portions of the site consists of thick, dead, fallen woody vegetation. Canopy closure in the site is variable, ranging from 25% in open areas to 70–90% in the denser vegetation. Soils in the majority of the site were dry, although a couple of small ponds and marshy areas along the cliff on the northeastern edge of the site contained water through July.

We detected one unpaired, male flycatcher in Site #5. Portions of the site not known to be occupied were surveyed five times, totaling 10.0 observer-hours. Cowbirds were detected on four surveys.

Upstream from Site #8

Area: 1.5 ha Elevation: 170 m

Vegetation in the majority of the site consists of an overstory of cottonwood and Goodding willow up to 15 m in height and an understory of tamarisk. The western third and southern edge of the site are vegetated by Goodding willow and cottonwood up to 10 m in height. The northern edge of the site

borders a cattail marsh. Canopy cover is variable and ranges from 50 to 80%. The central portion of the site was inundated throughout the breeding season.

We detected two breeding flycatchers. Portions of the site not known to be occupied were surveyed five times, totaling 4.0 observer-hours. Cowbirds were detected on three visits.

Planet Ranch Road

Area: 2.1 ha Elevation: 170 m

This mixed-native site follows the Bill Williams River at the southern edge of the riparian area. The northern bank of the river is steep and is vegetated by tamarisk and arrowweed perched well above the level of the river. The southern bank is more gradual, and beaver activity along the river has resulted in flooding on this bank. Vegetation on this side of the river consists of an overstory of Goodding willow and cottonwood up to 15 m in height and an understory of tamarisk 5 m in height. Overall canopy closure in this portion of the site is 70–90%. The river and the willow stand on the southern bank had surface water throughout the survey season.

No flycatchers were detected. We surveyed the site five times, totaling 5.8 observer-hours. We detected cowbirds on all surveys.

Ahakhav Tribal Preserve

The Ahakhav Tribal Preserve encompasses backwater areas along the Colorado River near Parker, Arizona, and includes restoration sites. We surveyed a portion of Deer Island.

Deer Island

Area: 15.2 ha Elevation: 104 m

This site consists of a narrow strip of mixed-native vegetation on the edge of a long backwater slough. The only dense, woody vegetation occurs in a strip approximately 5 m wide on the edge of the slough and consists of tamarisk and screwbean mesquite up to 6 m in height and an understory of arrowweed. More than 5 m from the water, vegetation is primarily arrowweed with widely scattered tamarisk and mesquite. Canopy closure is <50%. The southern side of the slough has a steep, high bank, and woody vegetation is perched several meters above the water level. The north bank is not as high, with woody vegetation approximately 1 m above the water level. Although extensive areas of inundated soils existed in the slough and the adjacent cattails, water did not extend into the woody vegetation at any time during the survey season. The majority of the site burned between 2 and 8 July, and surveys were discontinued.
We detected no willow flycatchers. We surveyed the site four times, totaling 4.0 observer-hours. Cowbirds were detected on all visits. No evidence of livestock use was observed.

CVCA Phase 1

Area: 26.2 ha Elevation: 73 m

This habitat creation area consists of a mosaic of rectangular cells of cottonwood, Goodding willow, and coyote willow of varying size and density. Each cell generally contains a single species and age class. The tallest cottonwoods and willows are around 9 m in height, and canopy closure in the densest areas is 80–90%. Coyote willow reaches 3–5 m in height. The site is flood irrigated but did not contain standing water during any of our site description visits. The Colorado River is about 100 m from the northern edge

of the site, and the remaining three sides are surrounded by agriculture. The irrigation canal adjacent to the site held surface water throughout the season.

We detected one willow flycatcher on 27 May. The site was surveyed five times, totaling 17.0 observer-hours. Large flocks of cowbirds were detected on all visits, and no evidence of livestock use was observed.

CVCA Phase 3

Area: 41.2 ha Elevation: 73 m

This habitat creation area consists of a mosaic of rectangular cells of cottonwood, Goodding willow, and coyote willow of varying size and density. The tallest cottonwoods reach 7–8 m, Goodding willow reach 6 m, and coyote willow reach 3 m. Canopy closure varies from 20 to 80%. The site is flood irrigated but did not contain standing water during any of our site description visits. The site is surrounded by agricultural fields. The irrigation canal adjacent to the site held water throughout the season.

We detected one willow flycatcher on 16 May, one on 27 May, and two on 10 June. The site was surveyed five times, totaling 15.8 observer-hours. Large flocks of cowbirds were detected on all visits, and no evidence of livestock use was observed.

Cibola Nature Trail

Area: 13.7 ha Elevation: 70 m

This habitat creation site consists of a mosaic of cottonwood, Goodding willow, and mesquite. Approximately half the site consists of scattered screwbean and honey mesquite up to 5 m in height with a thick understory of seep willow. The northern half of the site contains an extensive stand of Goodding willow 8 m in height. The northern edge of the willow stand has canopy closure <25% and many of the willow are dead. The southern half of the willow stand has canopy closure around 70%. The southwestern corner of the site has a small stand of cottonwoods, and stringers of cottonwoods up to 18 m in height occur throughout the site. The site is flood irrigated and contained varying amounts of surface water through the season.

We detected one willow flycatcher on 16 May, two on 27 May, and one on 10 June. The site was surveyed five times, totaling 4.6 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

Cibola Site #2 and Cibola Site #1

Cibola Site #2: Area: 16.4 ha Elevation: 65 m
Cibola Site #1: Area 7.7 ha Elevation: 65 m

These adjacent, mixed-exotic sites consist of a 200-m-wide strip of riparian vegetation between the channelized Colorado River to the west and a levee road to the east. Woody vegetation consists of a mix of tamarisk and arrowweed, 3–4 m in height, which is dry and scrubby on the eastern edge of the sites and becomes denser toward cattail marshes on the western edge of the sites. Emergent Goodding willow and cottonwood are scattered along the eastern edge of the marshes. Overall canopy closure is less than 50%. No surface water was present within the sites during the survey season.

We detected one willow flycatcher on 9 June at Cibola Site #1. We surveyed each site five times, totaling 7.1 hours at Cibola Site #2 and 5.3 hours at Cibola Site #1. Numerous cowbirds were detected on all surveys, and burros were observed using the periphery of the sites.

Hart Mine Marsh

Area: 31.6 ha Elevation: 65 m

This mixed-exotic site parallels the channelized Colorado River immediately south of Cibola Site #1. The site consists of a mix of tamarisk and linear stretches of marsh, which make up about 30% of the site. Height of the tamarisk does not exceed approximately 5 m, and reaches this height only within 20 m of the marshes. Away from the marshes, the tamarisk is 3 m in height and partially dead. Canopy closure within the densest tamarisk is 80–90%. An open channel had been dredged down the middle of the northern third of the site. The marshes contained standing water throughout the survey season, but water did not extend under the woody vegetation. The site lacks the height and extent of woody vegetation typical of occupied flycatcher habitat along the LCR, and surveys were discontinued in July.

No willow flycatchers were detected. We surveyed the site four times, for total of 7.8 observer-hours. Cowbirds were detected on all surveys and burros were observed on the periphery of the site.

Cibola Lake East

Area: 4.5 ha Elevation: 64 m

This site borders the marsh on the eastern edge of Cibola Lake. Vegetation within the site consists primarily of tamarisk. Within 30 m of the marsh edge, tamarisk reaches 6–7 m in height and 90% canopy closure. As distance from the marsh increases, the height and density of the tamarisk decreases, and the tamarisk becomes mixed with arrowweed. Soil within the site was dry throughout the survey season.
We detected one willow flycatcher on 4 June. We surveyed the site five times, totaling 6.3 observer-hours. Cowbirds were detected on all visits, and burro sign was observed on the periphery of the site.

Hoge Ranch

Area: 20.7 ha Elevation: 61 m

This mixed-exotic site is dominated by tamarisk 4–6 m in height, with a few emergent cottonwood and Goodding willow (15 to 18 m in height) at the southern end of the site near the old ranch. Linear marshes with cattail, bulrush, and common reed occupy less than 20% of the interior of the site, and there are a few patches of coyote willow. Canopy closure is variable and reaches 70–90% in areas of dense, woody vegetation. The marshes in the interior of the site contained small pools of water in July. The site also borders the Colorado River.

We detected three willow flycatchers on 20 May and one on 15 June. The site was surveyed five times, totaling 9.7 observer-hours. Cowbirds were detected on four surveys, and there was evidence of burros using the site.

Rattlesnake

Area: 7.6 ha Elevation: 60 m

AR063759

This mixed-exotic site is a patchwork of tamarisk 7 m in height with emergent Goodding willow up to 15 m in height and strips of dense coyote willow 6–8 m in height. Canopy closure is 70–90%. Extensive cattail marshes separate this site from the Colorado River. The interior of the site contained no standing water during the survey season.

We detected one willow flycatcher on 19 May. The site was surveyed five times, totaling 6.1 observer-hours. Cowbirds were detected on all surveys, and there was no evidence of livestock use.

Nursery NW

Area: 7.0 ha Elevation: 58 m

This mixed-exotic site lies between the Colorado River and a cattail marsh. The dominant vegetation is tamarisk approximately 5 m in height with an understory of common reed. Mesquite trees are scattered along the western edge of the site. The eastern edge of the site, adjacent to the cattail marsh, has a stand of Goodding willow 9 m in height. Overall canopy closure is around 70%, and the densest portions of the site have canopy closure >90%. Surface water was present in the adjacent marsh in May and June.

We detected one willow flycatcher on 16 June. The site was surveyed five times, totaling 4.4 observer-hours. Cowbirds were detected on all visits, and there was no evidence of livestock use.

Great Blue Heron

Area: 7.1 ha Elevation: 58 m

This site, on the eastern shore of Martinez Lake, consists of mixed-exotic vegetation. Near the shore of Martinez Lake, Goodding willow forms an overstory 15 m in height, with an understory of tamarisk, common reed, and giant reed (*Arundo* sp.). Canopy closure in this area is 80%. Portions of the site contain thickets of willow deadfall. Farther from the lake, the site is vegetated by scattered arrowweed and tamarisk 6 m in height, with canopy closure <50%. The site and the adjacent marsh were dry in May and June. Pools of water within the woody vegetation were noted in July after thunderstorms the previous night.

We detected one willow flycatcher on 28 May and one on 12 June. The site was surveyed five times, totaling 19.4 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Powerline

Area: 2.0 ha Elevation: 58 m

This mixed-native site consists of a strip of Goodding willow and cottonwood along the border of a cattail marsh. Overstory height is approximately 12 m and canopy closure is <50%. Tamarisk and arrowweed are present in the understory, and honey mesquite is mixed with the tamarisk on the upland edge of the site. Small pools of water were present within the marsh in May and July, but the marsh was dry in June. We detected one willow flycatcher on 28 May. We surveyed the site five times, totaling 6.3 observer-hours. Cowbirds were detected on all visits, and burro tracks and scat were noted within the site.

Martinez Lake

Area: 4.6 ha Elevation: 58 m

This mixed-native site borders the eastern shore of Martinez Lake. The eastern edge of the site, adjacent to the upland, is dominated by arrowweed with scattered Goodding willow, cottonwood, and tamarisk. Goodding willow <10 m in height and cottonwood up to 15 m in height are more prevalent on the western edge of the site, adjacent to cattails and common reed along the lakeshore. Canopy closure is highly variable. No surface water was recording within the site at any time during the survey season, and the marsh edge adjacent to the site was also dry.

No willow flycatchers were detected. We surveyed the site five times, totaling 6.0 observer-hours. Cowbirds were detected on all visits, and burro tracks and scat were observed at the site.

Gila River Site #2

Area: 5.1 ha Elevation: 45 m

The center of this mixed-native site consists of an overstory of cottonwood up to 15 m in height and Goodding willow approximately 8 m in height, with an understory of arrowweed. Canopy closure in the center of the site is 70–90%. The remainder of the site is vegetated by tamarisk 4 m in height and arrowweed, with canopy closure <50%. The site is bordered to the north by agricultural fields and to the south by an open, sandy area vegetated by arrowweed. There was no standing water within the vegetation during the survey season, but the northwestern edge of the site borders a marsh, which held water throughout the season.

We detected three willow flycatchers on 30 May and one on 14 June. The site was surveyed five times, totaling 8.2 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Fortuna Site #1

Area: 5.1 ha Elevation: 45 m

This mixed-native site consists of a narrow strip of cottonwood and Goodding willow up to 15 m in height with 50–70% canopy closure. Tamarisk and arrowweed form a patchy understory on the periphery of the site. Within the densest cottonwood/willow areas, there is little understory but many downed branches. The site is bordered to the north by agricultural fields and to the south by a cattail marsh and the Gila River. Surface water was recorded in the lowest portion of the site in May, but the entire site was dry in June and July.

We detected two willow flycatchers on 31 May. We surveyed the site five times, totaling 5.3 observer-hours. Large numbers of cowbirds were detected on all visits, and no evidence of livestock use was observed.

Fortuna North

Area: 3.4 ha Elevation: 46 m

This site is vegetated primarily by mature tamarisk approximately 7 m in height. Goodding willow and mesquite, also 7 m in height, are scattered throughout the site but make up less than 10% of the vegetation. Canopy closure is approximately 80%. The western edge of the site borders the Gila River. No surface water was noted within the site during the survey season.

We detected no willow flycatchers at this site. We surveyed the site five times, totaling 6.3 observer-hours. Large numbers of cowbirds were detected on all visits, and no evidence of livestock use was observed.

AR063762

CALIFORNIA

Palo Verde Ecological Reserve, PVER Phase 2

Area: 28.7 ha Elevation: 85 m

This habitat creation site is vegetated with a mosaic of cottonwood, Goodding willow, and coyote willow, which reach heights of 8, 7, and 4 m, respectively. Height and density of the vegetation varies within as well as between cells of the site. Canopy closure is highly variable, ranging from <25 to 80%. The entire site has a ground covering of alfalfa (*Medicado sativa*). The site is flood irrigated but did not contain surface water during any of our site description visits. The irrigation canal adjacent to the site contained water throughout the season.

We detected one willow flycatcher on 27 May and one on 3 June. We surveyed the site five times, totaling 15.0 observer-hours. Large numbers of cowbirds were detected on all visits, and no evidence of livestock use was recorded.

Big Hole Slough

Area: 29.0 ha Elevation: 82 m

This mixed-native site consists of cattail marshes edged with narrow bands of coyote willow 5 m in height. In upland areas away from the marshes, the site contains tamarisk and honey and screwbean mesquite up to 8 m in height with an understory of arrowweed. A few tall Goodding willow and cottonwood are present at the site. Overall canopy closure is approximately 50%. The site is surrounded by agricultural fields. The marsh contained standing water throughout the survey season.
We detected one willow flycatcher on 17 June. The site was surveyed five times, totaling 17.0 observer-hours. Cowbirds were detected on all visits, often in large flocks. No livestock use was observed.

Cibola Island

Area: 4.2 ha Elevation: 70 m

This mixed-native site is approximately 9.5 km southwest of Cibola Nature Trail. The site runs north to south, extending approximately 500 m lengthwise, with a width of 100 m. Dirt roads border the site to the north, east, and west. Open farm fields lie across the eastern road, with irrigation channels alongside the road. An irrigation canal empties into the northern end of the site, creating an open, marshy area down the center of the site. Between this marshy area and the western road, vegetation consists of an overstory of Goodding willow 10–12 m in height with an understory of tamarisk 5–7 m in height. Canopy closure within the willows is 80%. The eastern edge of the marsh is lined with a narrow strip of tamarisk 5–6 m in height with a few emergent Goodding willows on the marsh edge. Between the tamarisk strip and the eastern road, vegetation consists of honey mesquite and bushy arrowweed. The marsh was inundated with up to 50 cm of water in May, but in June and July the marsh contained only small pools.

We detected four willow flycatchers on 26 May and three on 4 June. The site was surveyed five times, totaling 5.1 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

AR063763

Walker Lake

Area: 11.4 ha Elevation: 64 m

This mixed-exotic site is located along the northeastern edge of Walker Lake. The majority of the site consists of very dense tamarisk approximately 5 m in height with 90% canopy closure. The southeastern end of the site contains scattered emergent Goodding willow up to 20 m in height, as well as a couple of emergent cottonwoods. This portion of the site also contains a small opening with dead cattails and a small patch of half-dead coyote willow. Walker Lake contained standing water and saturated soil throughout the survey season. Areas of the site adjacent to Walker Lake had saturated soils in May, though these soils were only damp in June and July. Soils in the interior of the site were dry throughout the survey season.

We detected no willow flycatchers. The site was visited five times, totaling 11.4 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

Paradise

Area: 7.8 ha Elevation: 62 m

The center of this mixed-native site consists of stringers of cottonwood and Goodding willow 15–20 m in height. Tamarisk (5 m in height) and arrowweed (3 m in height) make up the understory. The cottonwoods and willows are separated from the Colorado River by a narrow (50-m-wide) strip of dense tamarisk. A marsh borders the western side of the southern third of the site. This marsh had been vegetated by cattails in previous years but now consists primarily of common reed (*Phragmites australis*). Canopy closure within the site is variable. Standing water was present within the marsh in May.

We detected one willow flycatcher on 20 May. The site was surveyed five times, totaling 6.8 observer-hours. Cowbirds were detected on every visit, and burros were noted near the site.

Milemarker 65

Area: 10.0 ha Elevation: 58 m

The site is a narrow strip of mixed-exotic vegetation between the Colorado River and a backwater marsh. Vegetation at the site consists primarily of dense tamarisk 6 m in height. Dense common reed, approximately 3 m in height, also occurs throughout the site and together with the tamarisk creates almost complete canopy closure. Because of the impenetrable vegetation at the site, we surveyed it from the river, and hydrologic conditions in the interior of the site were unknown.

No willow flycatchers were detected. We surveyed the site five times for a total of 2.9 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Ferguson Lake

Area: 21.1 ha Elevation: 57 m

The Ferguson Lake site is on a strip of land between Ferguson Lake and the Colorado River. Vegetation is mixed-native, with scattered, emergent Goodding willow 10 m in height along the western edge of the site bordering Ferguson Lake. Tamarisk 5–6 m in height is the dominant understory species, and it forms a continuous canopy in portions of the site. The site also contains patches of arrowweed with scattered

AR063764

screwbean mesquite and little canopy cover. The northwestern corner of the site up to 50 m from the lakeshore had damp soils in May and standing water in June and July.

We detected three willow flycatchers on 21 May and two on 16 June. The site was surveyed five times, totaling 16.8 observer-hours. Cowbirds were detected on all visits, and no signs of livestock use were observed.

Mittry West

Area: 4.4 ha Elevation: 48 m

The center of this mixed-native site is dominated by Goodding willow 12 m in height with a dense understory of arrowweed and tamarisk. Canopy closure is approximately 80%. Honey and screwbean mesquite are scattered throughout the site but are more common near the periphery. Surface water was present in the site during May, but the site was dry in June and July and a small patch of cattails within the site was noted in June as being primarily dead.

We detected two willow flycatchers on 11 June. The site was visited five times, totaling 7.9 observer-hours. Cowbirds were detected during all surveys, and no evidence of livestock use was observed.

AR063765

COLOR-BANDING AND RESIGHTING

At monitoring sites in Nevada and Arizona, SWCA field personnel color-banded 17 new adult flycatchers and recaptured 8 individuals previously banded as adults (Table 3). An additional 55 adults were identified to individual via resighting, while 10 individuals were resighted but did not have their color combinations confirmed. One individual had federal band on one leg and an injury on the other leg, and one adult had a duplicate color-band combination. We detected eight individuals identified as returning nestlings by the presence of a single federal band, with three (38%) identified to individual via recapture. Thirty-one adult flycatchers remained unbanded, and banding status was undetermined (i.e., we were unable to determine if these individuals were banded) for 19 adults. We banded 44 nestlings from 21 nests. We banded flycatchers opportunistically at Key Pittman Wildlife Management Area and St. George, capturing and color-banding six new adults and recapturing one returning nestling; twelve nestlings from five nests were banded (Table 4).

For all captured adults and nestlings we collected blood samples.

Banding results by state and site are summarized below. For UTMs of captured and resighted individuals, please refer to the Presence/Absence Surveys section above (UTM coordinates presented are the centroid of each site).

Table 3. Willow Flycatchers Detected at All Monitored Study Areas with Resident Flycatchers, 2009 (Continued)

[1] PAHR = Pahranagat NWR, LIFI = Littlefield, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR.

[2] N/A = not applicable, INA = information not available.

[3] **Color-band codes**: EE = electric yellow federal band, PU = pumpkin federal band, Bs = blue federal band, XX = standard silver federal band, TQ = turquoise federal band, (M) = metal pin striped band, UB = unbanded, R = red, O = orange, Y = yellow, G = green, D = dark blue, B = light blue, V = violet, W = white, K = black, Z = gold, banded = bird was banded but combination could not be determined, undetermined = presence of bands could not be determined. Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band; color-band designations for right and left legs are separated with a colon.

[4] Old combination included only if rebanded in 2009.

[5] **Age in 2009**: L = nestling, HY = hatch year, SY = 2 years, AHY = 2 years or older, 3Y = 3 years, A3Y = 3 years or older, 4Y = 4 years, A4Y = 4 years or older, etc.

[6] **Sex codes**: M = male, F = female, U = unknown.

[7] **Territory or Location code**: Number without an alpha code indicates a flycatcher pair, T = territorial individual detected for at least 7 days, F = individual detected for less than 7 days. Number indicates unique location.

[8] **Observation status codes**: N = new capture, R = recapture followed by date recaptured, RS = resight.

[9] Right leg injured, but color-band could not be removed.

[10] Nestling suspected to have died before fledging.

[11] This federal band removed.

[12] Female mated consecutively with two different males.

[13] Band number likely 2390-92434 but cannot be confirmed because bird was not captured in 2009. Bird had visible injury on left leg.

[14] Color combination is a duplicate; federal band number and identify of flycatcher unknown.

[15] Right leg not banded because of preexisting injury.

[16] Fledgling found dead near nest.

[17] Nestling died before fledging.

[17] Original federal band 2370-40173.

[17] Recapture on 15 May was in a passive net at the Beal Lake MAPS station.

Table 4. Banded Willow Flycatchers, Non-Monitoring Sites, 2009

[5] **Sex codes**: M = male, F = female, U = unknown.

[6] **Observation status codes**: N = new capture, R = recapture followed by date recaptured, RS = resight.

[7] Original federal band number 2140-66690.

[8] Nestling died before fledging.

AR063777

NEVADA

Monitoring Sites

Pahranagat – We detected 21 resident, adult willow flycatchers from 12 territories at Pahranagat. In addition to resident adults, we detected three individuals for which residency and/or breeding status could not be confirmed. Of the 12 territories recorded at Pahranagat, 11 consisted of breeding pairs and 1 consisted of an unpaired male. Of the breeding individuals, one male was polygynous with two females, and one female mated consecutively with two males.

Field personnel captured and color-banded five new adults and recaptured six flycatchers previously captured as an adult. We resighted and confirmed band combinations for an additional 11 adults. Of the resighted adults, one was originally banded as a nestling in 2008. The presence of bands could not be determined for two adults. We banded 11 nestlings from five nests, and 2 of these nestlings were recaptured as fledglings. We resighted 13 unbanded fledglings from four additional nests.

Mesquite – We detected 25 resident, adult willow flycatchers from 14 territories at Mesquite. In addition to resident adults, we detected three individuals for which residency and/or breeding status could not be determined. Of the 14 territories recorded at Mesquite, 12 consisted of paired individuals and 2 consisted of unpaired males. Of the breeding individuals, two males were polygynous with two females and one female mated consecutively with two males.

Field personnel recaptured two flycatchers previously captured as adults. We confirmed the identities of an additional 14 adults via resighting. One additional adult had a federal band on one leg and an injury on the opposite leg, and another adult had a duplicate color combination. Of the resighted adults, four were originally banded as nestlings in 2008. Eight adults remained unbanded, and three adults were banded but band combinations could not be confirmed. We banded four nestlings from four nests.

Mormon Mesa – We detected 27 resident, adult willow flycatchers from 17 territories at Mormon Mesa. In addition to resident adults, we detected six individuals for which residency could not be confirmed. Of the 17 territories recorded at Mormon Mesa, 13 consisted of breeding individuals and 4 consisted of unpaired males. Of the breeding individuals, three males were each polygynous with two females.

Field personnel captured and color-banded two new adults. We resighted and identified 21 additional returning adults; of these, five were banded as nestlings in 2008. We captured one returning nestling originally banded as a juvenile in 2007 and resighted one additional returning nestling with a single federal band that we were unable to recapture. Four adults remained unbanded, and band combinations could not be confirmed for four adults. We banded 22 nestlings from nine nests. Three of these nestlings were known to have died before fledging. We resighted three unbanded fledglings from three nests.

Muddy River – We detected 13 resident, adult willow flycatchers from eight territories at Muddy River. In addition to resident adults, we detected four individuals for which residency could not be confirmed. Of the eight territories recorded, six consisted of breeding individuals and two consisted of unpaired males. Of the resident individuals, one female mated consecutively with two males, both of which were consecutively mated with two females.

AR063778

Field personnel captured and color-banded two new adults. We resighted and identified four other adults, three of which were banded as nestlings in 2008. We resighted one adult for which the band combination could not be confirmed. We resighted two returning nestlings with single federal bands but could not capture these individuals to determine year and study area of origin. Seven adults remained unbanded, and band status could not be determined for one individual. We banded one nestling, which died before fledging.

Non-Monitoring Sites

These study areas were monitored by other agencies, and here we report only banded flycatchers that were captured or resighted. Unbanded individuals or those with unknown band status are not included.

Key Pittman Wildlife Management Area – Field personnel captured and color-banded two new adults. We resighted and identified four returning banded adults. We banded seven nestlings from three nests.

St. George – Field personnel captured and color-banded four new adults. We resighted and identified two adult flycatchers, one of which was banded as a nestling in 2008. We recaptured another adult that was banded as a nestling in 2001 and had not been identified since. Another adult was identified as a returning nestling, but we were unable to capture this individual to determine year and study area of origin. We banded five nestlings from two nests; four of these died before fledging.

ARIZONA

Littlefield – We detected four resident, adult willow flycatchers from three territories at Littlefield. In addition to resident adults, we detected one individual for which residency and/or breeding status could not be confirmed. Of the three territories, two consisted of breeding pairs and one consisted of an unpaired male. Of the breeding individuals, one male was polygynous with two females.

Field personnel captured and color-banded one new adult. We resighted and confirmed band combinations for an additional adult, which was originally banded as a nestling in 2008. One resident adult remained unbanded, and band status could not be determined for another. Band status could not be determined for the individual for which residency and/or breeding status could not be confirmed.

Topock – We detected 14 resident, adult willow flycatchers from 13 territories at Topock. In addition to resident adults, we detected 14 individuals for which residency and/or breeding status could not be confirmed. Of the 13 territories recorded at Topock, 1 consisted of paired individuals and 9 consisted of unpaired males. In each of the remaining three territories, a singing male was detected throughout the breeding season and an unchallenged flycatcher, suspected to be a female, was detected for only a few days in June.

Field personnel captured and color-banded one new adult and resighted and identified two other banded adults. We captured two returning nestlings originally banded in 2007 and resighted but were unable to recapture two additional returning nestlings with single federal bands. Seven adults remained unbanded, and the band status of 12 individuals could not be determined. The color combinations of two banded adults could not be confirmed. We banded three nestlings from one nest.

Bill Williams – We detected 13 resident willow flycatchers from eight territories at Bill Williams. In addition to resident adults, we detected two individuals for which residency and/or breeding status could not be determined. Of the eight territories recorded at Bill Williams, five consisted of paired individuals, two consisted of unpaired males, and in the remaining territory a singing male was detected through most of June and an unchallenged flycatcher, suspected to be a female, was detected for only a few days in June.

Field personnel captured and color-banded six new adults. We resighted and identified three returning banded adults. Four adults remained unbanded, and band status could not be determined for two adults. We banded three nestlings from one nest and resighted three unbanded fledglings from another nest.

AR063780

NEST MONITORING

In Nevada and Arizona, we documented 72 willow flycatcher nesting attempts, 65 of which contained eggs and were used in calculating nest success and productivity (Table 5). Twenty-three (35%) nests were successful and fledged young; 40 (62%) failed, and fate was unknown for 2 (3%). Mayfield survival probability ranged from 0.053 to 0.519 and was 0.368 for all sites combined. Depredation was the major cause of nest failure, accounting for 40% of all failed nests and 48% of nests that failed after flycatcher eggs were laid.

Sixteen of 56 nests (17%) with flycatcher eggs and known contents were brood parasitized by Brown-headed Cowbirds. Brood parasitism at all study areas ranged from 0 to 100% and was highest at Littlefield. We observed the seventh consecutive year of no brood parasitism at Pahranagat. Nests that contained flycatcher eggs and were brood parasitized were less likely to fledge flycatcher young than nests that were not parasitized.

Nest monitoring results by site are summarized below. For UTMs, please refer to the Presence/Absence Surveys section above (UTM coordinates presented are the centroid of each site).

[1] PAHR = Pahranagat NWR, LIFI = Littlefield, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR.

[2] WE = willow flycatcher egg.

[3] Only nests with at least one flycatcher egg were used in percentage calculations. Percentages are given in parentheses.

[4] Parasitized nests include all nests that contained at least one flycatcher egg and one cowbird egg, regardless of nest fate. Percentages include only nests with at least one flycatcher egg and for which contents could be determined.

Re: SW Willow Flycatcher Studies 2008
T&E Species Permit TE028605-1, Final Permit Report Deliverable

Ms. Marquez:

In fulfillment of SWCA Environmental Consultant's Federal Fish and Wildlife permit (TE028605-1) deliverable requirement with your department, please find enclosed on CD an annual report titled *Southwestern Willow Flycatcher Surveys, Color-banding and Nest Monitoring in Nevada, California, and Arizona,* 2008. This report details all of our Southwestern Willow Flycatcher studies conducted in California in 2008, and is presented in a site-by-site format to facilitate locating information of interest.

If you or your department requires any additional information, please do not hesitate contacting me directly: (928) 774-5500 ext. 201; tkoronkiewicz@swca.com.

Many thanks for your continuing support, sincerely,

Tom Koronkiewicz

EXECUTIVE SUMMARY

The Southwestern Willow Flycatcher (*Empidonax traillii extimus*), listed as federally endangered in 1995, breeds in dense, mesic riparian habitats at scattered, isolated sites in New Mexico, Arizona, southern California, southern Nevada, southern Utah, southwestern Colorado, and, at least historically, extreme northwestern Mexico. Historical breeding records and museum collections indicate a sizable population of Southwestern Willow Flycatchers may have existed along the extreme southern stretches of the lower Colorado River region. Factors contributing to the decline of flycatchers on the breeding grounds include loss, degradation, and/or fragmentation of riparian habitat; invasion of riparian habitat by nonnative plants; and brood parasitism by Brown-headed Cowbirds (*Molothrus ater*).

Willow flycatcher studies have been conducted along the Virgin and lower Colorado Rivers and tributaries annually since 1996, in compliance with requirements set forth by the U.S. Fish and Wildlife Service (USFWS) regarding U.S. Bureau of Reclamation (Reclamation) routine operations and maintenance along the lower Colorado River. Biological Assessments and the resulting Biological Opinions on operations and maintenance were prepared as steps to developing a Multi-Species Conservation Program (MSCP) for long-term endangered species compliance and management in the historical floodplain of the lower Colorado River (LCR). The LCR MSCP calls for continued surveys and monitoring of willow flycatchers along the lower Colorado River. The LCR MSCP was signed in April 2005, and implementation of the program began in October 2005.

Reclamation and USFWS completed a separate consultation on the potential effects to threatened and endangered species from implementation of surplus guidelines through 2016 and an annual change in the point of diversion for up to 400,000 acre-feet of California apportionment water for 75 years. The point of diversion, previously located below Parker Dam, would change to a point above Parker Dam. These changes in water regulation could cause a drop in floodplain groundwater levels of 1.55 feet (0.47 m) or less and have the potential to modify riparian habitats below Parker Dam. A Biological Opinion for Interim Surplus Criteria, Secretarial Implementation Agreements, and Conservation Measures was issued in January 2001 and required monitoring of 150.5 ha of existing, occupied Southwestern Willow Flycatcher habitat between Parker and Imperial Dams. In 2004, Reclamation biologists initiated studies of the microclimate within potentially affected areas. In 2005, these studies were continued and expanded by SWCA Environmental Consultants (SWCA) to address how the hydrological changes might affect riparian habitats along the Parker to Imperial reach.

From 1997 to 2008, breeding populations of Southwestern Willow Flycatchers were documented along the Virgin and lower Colorado Rivers and tributaries at eight study areas from Pahranagat National Wildlife Refuge, Nevada, south to the Bill Williams River in Arizona. Willow flycatchers also have been detected during the breeding season at many sites along the Colorado River south of the Bill Williams River to the Mexico border. Behavioral observations and timing of detections strongly suggest this section of the river corridor is a major flyway for migrant willow flycatchers in spring. The degree to which migrant Southwestern Willow Flycatchers use the lower Colorado River corridor is unknown.

SWCA was contracted by Reclamation to continue surveys, monitoring, and demographic and ecological studies of the Southwestern Willow Flycatcher in suitable and/or historical riparian and wetland habitats throughout the Virgin and lower Colorado River regions in 2008. Approximately 100 sites are included in the study, but a portion of them are surveyed on a biennial basis. We completed presence/absence surveys and site descriptions at 77 sites in 16 study areas from the Pahranagat National Wildlife Refuge (NWR), Nevada, south to Yuma, Arizona. We also conducted more intensive studies at the eight study areas where territorial flycatchers were detected: Pahranagat NWR, Mesquite, Mormon Mesa, and Muddy River Nevada; and Grand Canyon, Topock Marsh, Bill Williams River NWR, and Ahakhav Tribal Preserve, Arizona. At these study areas, we searched for nests in all areas occupied by territorial

flycatchers, monitored willow flycatcher nests to document nest fate, brood parasitism, and causes of nest failure; color-banded and resighted as many willow flycatchers as possible to determine the breeding status of territorial flycatchers and document movement and recruitment; and measured characteristics of vegetation and microclimate in occupied territories and at old flycatcher nests in abandoned areas where we had collected similar data when the nest was active.

We used recorded broadcasts of willow flycatcher song and calls to elicit responses from willow flycatchers at 77 sites, ranging in size from 1 to 92 ha, along the Virgin and lower Colorado Rivers and tributaries between 12 May and 28 July 2008, following a 5-survey protocol. We detected willow flycatchers on at least one occasion at 42 of these sites. Resident, breeding flycatchers were detected at nine sites within the following six study areas: Pahranagat NWR, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams. Resident flycatchers were also detected at Grand Canyon and Ahakhav, Arizona. South of Ahakhav, 90 willow flycatcher detections were recorded between 15 May and 22 June; no flycatcher detections were recorded at any of these sites after 22 June. Monitoring results suggest these flycatchers were not resident, breeding individuals and were most likely spring migrants.

We used targeted mist-net and passive netting techniques to capture and uniquely color-band adult and fledgling willow flycatchers at all survey sites where resident willow flycatchers were detected. Nestlings were banded between 8 and 10 days of age. We banded each willow flycatcher with a single, numbered U.S. federal aluminum band on one leg and one pin-striped, aluminum band on the other. We used binoculars to determine the identity of previously color-banded flycatchers by observing, from a distance, the unique color combinations on their legs.

We color-banded 18 new adult flycatchers and recaptured 6 individuals previously banded as adults. An additional 50 adults were identified to individual via resighting, while 4 individuals were resighted but did not have their color combinations confirmed, and 1 individual had federal band on one leg and an injury on the other leg. We detected 14 individuals identified as returning nestlings by the presence of a single federal band, with 4 (29%) identified to individual via recapture. Twenty-five adult flycatchers remained unbanded, and banding status was undetermined (i.e., we were unable to determine if these individuals were banded) for 17 adults. We banded 74 nestlings from 29 nests. We banded flycatchers opportunistically at Key Pittman Wildlife Management Area, Seegmiller Marsh, and Las Vegas Wash, capturing and color-banding 10 new adults and recapturing 3 returning nestlings. Eleven nestlings from four nests were banded.

We recorded 72 territories at all monitored sites. Of these, 50 (69%) consisted of paired flycatchers and 22 (31%) consisted of unpaired individuals. Ten breeding males were polygynous; nine were paired with two females, and one was paired with three females. One female mated consecutively with two different males.

Of the 95 adult willow flycatchers identified to individual in 2007, 54 (57%) returned in 2008; 3 (6%) were detected at a different study area from where they were detected in 2007. We detected two within-year, between-study area movements in 2008. One male moved from Pahrangat North to Key Pittman, and one female moved from Mormon Mesa Virgin River #2 to Muddy River Overton WMA.

Of the 50 juveniles banded in 2007, 2 (4%) were recaptured or resighted and identified in 2008. Both were detected at a different study area from where originally banded. Two individuals originally banded as nestlings in 2005 and two banded in 2006 were also recaptured; of these, three returned to a different study area than where originally banded. The median dispersal distance for all returning juvenile flycatchers in 2008 was 30 km.

We documented 62 willow flycatcher nesting attempts, 55 of which contained eggs and were used in calculating nest success and productivity. Thirty (55%) nests were successful and fledged young; 23 (42%) failed, and fate was unknown for 2 (3%). Mayfield survival probability ranged from 0.194 to 0.705 and was 0.461 for all sites combined. Depredation was the major cause of nest failure, accounting for 40% of all failed nests and 52% of nests that failed after flycatcher eggs were laid.

Eight of 48 nests (17%) with flycatcher eggs and known contents were brood parasitized by Brown-headed Cowbirds. Brood parasitism at all study areas ranged from 0 to 57% and was highest at Muddy River. We observed the sixth consecutive year of no brood parasitism at Pahranagat. Nests that contained flycatcher eggs and were brood parasitized were not less likely to fledge flycatcher young than nests that were not parasitized.

At Mesquite, Mormon Mesa, Muddy River, Topock Marsh, Bill Williams, and Ahakhav, we gathered data on vegetation and microclimate characteristics at one location for each of 41 territorial male flycatchers we identified, regardless of the length of time the male was resident and whether or not he obtained a mate. We delineated the following habitat types: 1) coyote willow, 2) tamarisk with coyote willow, 3) Goodding willow, 4) Goodding willow with tamarisk understory, 5) tamarisk with scattered Goodding willow, 6) tamarisk, and 7) tamarisk with mesquite. Coyote willow and Goodding willow are the only habitat types likely to be created at restoration areas, but we summarize vegetation and microclimate characteristics for all habitat types. Sample sizes in 2008 are likely too small to provide an accurate representation of the range and variance in vegetation and microclimate characteristics in each habitat type.

Territories within all vegetation types exhibited moist or inundated soil conditions throughout the breeding season. Several habitat types showed a general drying trend in soil conditions as the breeding season progressed. Daily maximum temperatures spanned a range of approximately 15°C among habitat types while daily minimum temperatures spanned only 5°C. Habitat types with high daily maximum temperatures also tended to have low daily minimum temperatures and thus had the largest temperature ranges. In general, habitats with a significant native component tended to be cooler and more thermally moderate than those dominated by tamarisk.

In addition to collecting vegetation and microclimate data at occupied territories, we investigated whether changes in vegetation and microclimate might have contributed to the abandonment of some areas by flycatchers. We identified several areas that had been occupied by nesting flycatchers in at least one previous year from 2003 to 2007 but were unoccupied in 2008, and we relocated old nests at which we had collected vegetation and microclimate information in the year the nest was active. We resampled microclimate and vegetation at these nests in 2008. At Mesquite and Mormon Mesa, areas that had been abandoned were affected by flooding over the 2004–2005 winter, and we had noted the loss of native vegetation in these areas. These qualitative observations were supported by the vegetation data collected in 2008, which showed shorter canopy height, less canopy closure, and less native vegetation than when the nests were active. We observed corresponding changes in microclimate, with generally higher temperatures recorded in 2008.

We had not noted qualitative changes in vegetation in abandoned areas at Muddy River or Topock, though vegetation data showed a decrease in live stems <2.5 cm dbh, an increase in dead foliage density at nest height, and a decrease in the percent of native vegetation at Muddy River. There were no statistically significant changes in microclimate at Muddy River, though the direction of interannual change was consistent with what we observed at Mesquite. Bulldozing activities in the vicinity of the nests at Muddy River could have contributed to abandonment of the area, or the site could have been unoccupied in 2008 as the result of interannual variation in site occupancy. Monitoring of the site in

future years will help determine whether abandonment of the site was a temporary or long-term phenomenon.

We detected a decrease in the number of live stems 2.5–8 cm dbh and a decrease in dead foliage below the nest at Topock. A decrease in the number of live stems at Topock could reduce suitability of the sites for flycatchers. The microclimate changes observed at Topock were in a direction opposite to what we anticipated, with old nest sites being generally cooler and more humid in 2008 than when they were active. The number of territories at Topock has varied widely over the years, and the abandonment of certain sites may simply reflect a lower overall number of territorial flycatchers rather than a change in habitat suitability.

In 2005, we selected 11 sites between Parker and Imperial Dams for inclusion in the habitat monitoring study addressing how changes in water transfer actions might affect riparian habitat. We also selected two control sites above Parker Dam and two below Imperial Dam. At each site we installed 3–5 temperature/humidity data loggers and one groundwater observation well (piezometer). All logger and piezometer locations selected in 2005 were retained in 2006. Two loggers and one piezometer were damaged or destroyed in a fire in December 2006 and were replaced in 2007, and one piezometer that was destroyed by a bulldozer in 2007 was replaced in 2008. Soil moisture measurements were collected at each data logger location during each of approximately five flycatcher surveys between 15 May and 25 July. Vegetation measurements were also collected at each data logger location after surveys were completed.

Daily, weekly, and seasonal cycles in groundwater levels were apparent. Groundwater levels drop during afternoon hours when evapotranspiration is high and on the weekends when water releases from Parker Dam decline. The seasonal cycle in groundwater levels mirrors the seasonal fluctuation in river flow.

Analyses of groundwater data indicate a strong correlation between piezometer water levels and releases from Parker Dam. Data did not show strong correlations between piezometer water level and soil moisture within the habitat monitoring sites. Most microclimatic variables at the combined habitat monitoring sites differed significantly from those at Topock Marsh. Topock was cooler and exhibited lower diurnal/nocturnal relative humidity and lower diurnal/nocturnal vapor pressure than habitat monitoring sites.

Comparisons of microclimate characteristics among 2005, 2006, 2007, and 2008 at the habitat monitoring sites indicated generally hotter and more humid conditions in 2006 than in the other years. The interannual changes were generally similar between test and control sites, suggesting that changes in temperature and humidity conditions may have been regional, rather than being influenced by changes in river operations. Soil moisture was lower in 2006 than in 2005 or 2007, and while this pattern was exhibited at both test and control sites, the interannual change was greater at control than at test sites. In 2008, soil moisture at test sites increased while it remained the same at control sites. This suggests that local conditions, in addition to regional climatic conditions, influenced soil moisture.

We noted between-year differences at the habitat monitoring sites for canopy closure, woody ground cover, and number of dead stems 2.5–8 cm dbh. There was no evidence that the differences in canopy closure and number of dead stems 2.5–8 cm dbh occurred exclusively at control sites or at test sites; rather, the differences occurred across all sites. Across all sites, canopy closure decreased between 2005 and 2006 and then increased in 2007 and 2008 to values higher than those recorded in 2005. The number of dead stems 2.5–8 cm dbh was lower in 2006 and 2007 than in 2005 or 2008. Percent woody ground cover was higher in 2008 than in previous years. There was a significant interaction between year and location for woody ground cover, with woody ground cover increasing at control plots between 2005 and 2006 and then decreasing in 2007 while it did not change at test plots across those years.

There were no between-year differences for live vertical foliage density in any meter interval, but there were between-year differences for the first, second, third, and fourth meter intervals above the ground for dead vegetation. In all cases, density of dead vegetation was higher in 2008 than in 2007. There was a significant interaction between live vertical foliage density and location for the fourth meter interval, but there was no clear pattern. There was also a significant interaction between dead vertical foliage density and location for the first meter interval, with the density of dead vegetation increasing more in 2007 and 2008 at control plots relative to test plots.

Chapter 1

INTRODUCTION

PROJECT HISTORY

In 1995, the U.S. Bureau of Reclamation (Reclamation), other federal, state, and tribal agencies, and environmental and recreational interests agreed to form a partnership to develop and implement a Multi-Species Conservation Program (MSCP) for long-term endangered species compliance and management in the historical floodplain of the lower Colorado River (LCR). As a step to developing the LCR MSCP, Reclamation prepared a Biological Assessment (BA) in August 1996, evaluating the effects of dam operations and maintenance activities on threatened, endangered, and sensitive (TES) species. These species included the Southwestern Willow Flycatcher (*Empidonax traillii extimus*), which was listed by the U.S. Fish and Wildlife Service (USFWS) as endangered in 1995 (60 FR 10694–10715). In response to the BA, the USFWS issued a Biological Opinion (BO) in April 1997 outlining several terms and conditions Reclamation must implement in order not to jeopardize the species. Among these terms and conditions was the requirement to survey and monitor occupied and potential habitat for Southwestern Willow Flycatchers along the lower Colorado River for a period of five years. The studies were intended to determine the number of willow flycatcher territories, status of breeding pairs, flycatcher nest success, the biotic and abiotic characteristics of occupied willow flycatcher sites, and Brown-headed Cowbird (*Molothrus ater*) brood parasitism rates. In 2002, Reclamation reinitiated consultation with USFWS on the effects of continued dam operations and maintenance on TES species along the lower Colorado River. The USFWS responded with a BO in April 2002 requiring continued Southwestern Willow Flycatcher studies along the lower Colorado River through April 2005. The BO also required implementation of a study to evaluate the effectiveness of Brown-headed Cowbird trapping for conservation of the flycatcher.

Reclamation and USFWS completed a separate consultation on the potential effects to threatened and endangered species from implementation of surplus guidelines through 2016 and an annual change in the point of diversion for up to 400,000 acre-feet for 75 years. A Biological Opinion for Interim Surplus Criteria, Secretarial Implementation Agreements, and Conservation Measures was issued in January 2001 and required monitoring of 150.5 ha of existing, occupied Southwestern Willow Flycatcher habitat between Parker and Imperial Dams.

The LCR MSCP is a 50-year program that seeks to protect 26 TES species and their habitats along the lower Colorado River while maintaining river regulation and water management required by law. The LCR MSCP was approved in April 2005 with the signing of a Record of Decision by the Secretary of the Department of the Interior, and implementation of the program began in October 2005. Documentation for the LCR MSCP includes a Habitat Conservation Plan (HCP), BA/BO, and an Environmental Impact Statement. The HCP specifies monitoring and research measures that call for surveys and research to better define habitat requirements for the Southwestern Willow Flycatcher and studies to determine the effects of cowbird nest parasitism on flycatcher reproduction.

Reclamation initiated willow flycatcher studies along the lower Colorado River in 1996, in anticipation of the requirements outlined in the BOs that were part of LCR MSCP development. These studies have been conducted annually since 1996. In compliance with the consultation on Interim Surplus Criteria and Secretarial Implementation Agreements, Reclamation biologists deployed temperature/humidity data loggers in 2004 at a subset of sites currently monitored for Southwestern Willow Flycatcher along the Colorado River in California and Arizona. These studies were expanded in 2005 to include annual monitoring of groundwater levels, vegetation, and soil moisture in addition to temperature and humidity.

SPECIES INTRODUCTION

The Southwestern Willow Flycatcher is one of four subspecies of willow flycatcher currently recognized (Unitt 1987), although Browning (1993) posits a fifth subspecies (*E. t. campestris*) occurring in the central portions of the United States (Figure 1.1). The Southwestern Willow Flycatcher breeds in dense, mesic riparian habitats at scattered, isolated sites in New Mexico, Arizona, southern California, southern Nevada, southern Utah, southwestern Colorado, and, at least historically, extreme northwestern Mexico and western Texas (Unitt 1987).

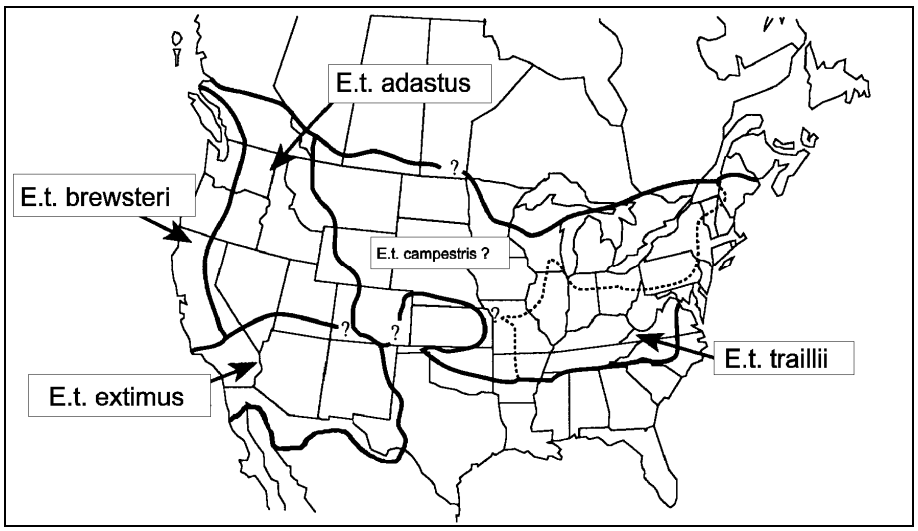

Figure 1.1. Breeding range distribution of the subspecies of the willow flycatcher (***Empidonax traillii***). Adapted from Unitt (1987), Browning (1993), and Sogge et al. (1997).

In the Southwest, most willow flycatcher breeding territories are found within small breeding sites containing five or fewer territories (Durst et al. 2006). One of the last long-distance Neotropical migrants to arrive in North America in spring, Southwestern Willow Flycatchers have a short, approximately 100-day breeding season, with individuals typically arriving in May or June and departing in August (Sogge et al. 1997). All four subspecies of willow flycatchers spend the non-breeding season in portions of southern Mexico, Central America, and northwestern South America (Stiles and Skutch 1989, Ridgely and Tudor 1994, Howell and Webb 1995, Unitt 1997), with wintering ground habitat similar to the breeding grounds (Lynn et al. 2003). Willow flycatchers have been recorded on the wintering grounds from central Mexico to southern Central America as early as mid-August (Stiles and Skutch 1989, Howell and Webb 1995), and wintering, resident individuals have been recorded in southern Central America as late as the end of May (Koronkiewicz et al. 2006b).

Historical breeding records and museum collections indicate that a sizable population of Southwestern Willow Flycatchers may have existed along the extreme southern stretches of the lower Colorado River region (Unitt 1987). However, no nests have been located south of the Bill Williams River, Arizona, in over 65 years (Unitt 1987), though northbound and southbound migrant willow flycatchers use the riparian corridor (Phillips et al. 1964, Brown et al. 1987, McKernan and Braden 2002, McLeod et al. 2008a, this document). Factors contributing to the decline of flycatchers on the breeding grounds include loss, degradation, and/or fragmentation of riparian habitat; invasion of riparian habitat by nonnative plants; and brood parasitism by Brown-headed Cowbirds (USFWS 1995, Marshall and Stoleson 2000). Because of low population numbers range-wide, identifying and conserving willow flycatcher breeding sites is thought to be crucial to the recovery of the species (USFWS 2002).

From 1997 to 2008,[1] breeding populations of Southwestern Willow Flycatchers were documented at eight study areas along the Virgin and lower Colorado Rivers and tributaries: (1) Pahranagat National Wildlife Refuge (NWR), Nevada; (2) Beaver Dam Wash/Virgin River confluence at Littlefield, Arizona; (3) Mesquite and (4) Mormon Mesa on the Virgin River, Nevada; (5) Overton Wildlife Management Area (WMA) along the Muddy River, Nevada; (6) Grand Canyon, Arizona; (7) Topock Marsh on the Colorado River, Havasu NWR, Arizona; and (8) Bill Williams River NWR (Bill Williams), Arizona (McLeod et al. 2008a, Braden and McKernan unpubl. data). Willow flycatchers, including one banded migrant Southwestern Willow Flycatcher (Koronkiewicz et al. 2006a), were detected during the breeding season at several sites along the Colorado River south of the Bill Williams River to the Mexico border, but no nesting activity was confirmed.

PURPOSE AND DESCRIPTION OF STUDY

The purpose of the 2008 study is to continue surveys, monitoring, and demographic and ecological studies of the Southwestern Willow Flycatcher in suitable and/or historical riparian and wetland habitats throughout the lower Colorado and Virgin River region. This project encompasses three types of studies: (1) presence/absence surveys, including site descriptions, at pre-selected sites along the lower Colorado and Virgin Rivers and tributaries, including the lower Grand Canyon and Bill Williams River; (2) intensive life history studies at all study areas where breeding flycatchers are located to assess Southwestern Willow Flycatcher demographics and ecology, habitat selection, and the effects of Brown-headed Cowbird brood parasitism; and (3) monitoring of microclimate, vegetation, and groundwater conditions of currently occupied[2] Southwestern Willow Flycatcher habitat between Parker and Imperial Dams. SWCA's contract specifies the following field tasks:

Presence/absence Surveys. At approximately 100 sites along the lower Colorado River, conduct presence/absence surveys, following a 5-survey protocol (per USFWS 2000).

Site Descriptions. Provide a general site description for each site, including major types of vegetation and hydrological conditions, at least three times during the survey period.

Nest Monitoring. Search for nests in all areas occupied by territorial flycatchers, and monitor all nests to determine nest fate, brood parasitism, and causes of nest failure.

Banding. Band as many adult and juvenile flycatchers as possible at sites with territorial flycatchers.

Vegetation, Soils, and Microclimate. Collect vegetation, soil, and microclimate data at the within-territory level at breeding locations in order to quantify conditions at flycatcher territories for replication at restoration areas.

Habitat Monitoring. At 15 previously identified sites, monitor vegetation, microclimate, and groundwater conditions to determine how these may be affected by water transfers.

[1] Studies in 1996 did not include any sites in Nevada.

[2] As per Reclamation (1999), we defined occupied Southwestern Willow Flycatcher habitat as patches of vegetation that are similar to and contiguous with areas where willow flycatchers were detected after 15 June in any year, 1996–2007.

Each distinct aspect of the 2008 study is addressed in a separate chapter in this report, as follows:

Chapter 2 – Presence/absence Surveys and Site Descriptions. This chapter presents the methodology and results for presence/absence surveys and gives a general site description for each survey site.

Chapter 3 – Color-banding and Resighting. Details of banding activities in 2008 and resighting of previously banded flycatchers are presented in this chapter. Also included are discussions of within- and between-year movement of individual flycatchers.

Chapter 4 – Nest Monitoring. This chapter summarizes nesting attempts, nest fates, and productivity for all Southwestern Willow Flycatcher nesting activity.

Chapter 5 – Vegetation Sampling. Vegetation sampling methods are described, and vegetation characteristics are summarized for territories in different habitat types. We also compare vegetation characteristics at nest sites when the nest was active vs. vegetation at the same location after the area had been abandoned by flycatchers.

Chapter 6 – Microclimate. The methodology of monitoring temperature, humidity, and soil moisture is described, and microclimate characteristics are summarized for flycatcher territories in different habitat types. We also compare microclimate characteristics at nest sites when the nest was active vs. microclimate at the same location after the area had been abandoned by flycatchers.

Chapter 7 – Habitat Monitoring. The methodology and results of monitoring microclimate, vegetation, and groundwater conditions at occupied sites between Parker and Imperial Dams are presented.

Chapter 2

PRESENCE/ABSENCE SURVEYS AND SITE DESCRIPTIONS

INTRODUCTION

Broadcasts of recorded conspecific vocalizations are useful in eliciting responses from nearby willow flycatchers, and multiple broadcast surveys conducted throughout the breeding season are the standard technique for determining the presence or absence of ***E. t. extimus*** (Sogge et al. 1997). According to Sogge et al. (1997) and USFWS (2002), willow flycatchers detected between approximately 15 June and 20 July in the breeding range of ***E. t. extimus*** probably belong to the southwestern subspecies. However, because northbound individuals of all western subspecies of the willow flycatcher migrate through areas where ***E. t. extimus*** are actively nesting, and southbound migrants occur where ***E. t. extimus*** are still breeding (Sogge et al. 1997, USFWS 2002), field confirmation of the southwestern subspecies is problematic.[1] For example, the northwestern ***E. t. brewsteri***, far more numerous than ***E. t. extimus***, has been documented migrating north in southern California as late as 20 June (Garrett and Dunn 1981 as cited in Unitt 1987), and Phillips et al. (1964 as cited in Unitt 1987) documented ***E. t. brewsteri*** collected in southern Arizona on 23 June. An understanding of willow flycatcher migration ecology in combination with multiple broadcast surveys conducted throughout the breeding season is therefore needed to assess the presence and residency of Southwestern Willow Flycatchers.

Migration routes used by ***E. t. extimus*** are not well documented, though more is known of northbound migration in spring than the southbound migration in fall because flycatchers are more vocal in spring and can therefore be distinguished from other ***Empidonax*** species. During northbound migration, all subspecies of willow flycatchers use riparian habitats similar to breeding habitat along major river drainages in the Southwest such as the Rio Grande (Finch and Kelly 1999), Colorado River (McKernan and Braden 1999), San Juan River (Johnson and Sogge 1997), and the Green River (M. Johnson unpubl. data). Although migrating willow flycatchers may favor young, native willow habitats (Yong and Finch 1997), migrants are also found in both spring and fall in a variety of habitats that are unsuitable for breeding. These migration stopover habitats, even though not used for breeding, are likely important for both reproduction and survival. For most long-distance Neotropical migrant passerines, migration stopover habitats are needed to replenish energy reserves to continue northbound or southbound migration.

In 2008, we completed multiple broadcast surveys at sites in 16 study areas[2] along the lower Colorado River and its tributaries to detect both migrant and resident willow flycatchers (Figure 2.1).

Special Concern Species

The Yuma Clapper Rail (***Rallus longirostris yumanensis***) is listed as federally endangered by the USFWS, and the Yellow-billed Cuckoo (***Coccyzus americanus occidentalis***) is a candidate for federal listing. Both species occur along the lower Colorado River and its tributaries and are of concern to managing agencies. Nine additional avian species [California Black Rail (***Laterallus jamaicensis coturniculus***), Western Least Bittern (***Ixobrychus exilis***), Elf Owl (***Micrathene whitneyi***), Gila Woodpecker (***Melanerpes uropygialis***), Gilded Northern Flicker (***Colaptes auratus chrysoides***), Vermilion Flycatcher (***Pyrocephalus rubinus***),

[1] Throughout this document, the terms "flycatcher" and "willow flycatcher" refer to ***E. t. extimus*** when individuals are confirmed as residents. For individuals for which residency is undetermined, subspecies is unknown.

[2] Study areas consist of 1–20 survey sites that are grouped geographically (see Table 2.2).

Figure 2.1. Locations of Southwestern Willow Flycatcher study areas along the lower Colorado River and tributaries, 2008. (Note, study area labels represent the approximate center of multiple sites within that region; see Table 2.2)

Arizona Bell's Vireo (*Vireo bellii arizonae*), Yellow Warbler (*Dendroica petechia*), and Summer Tanager (*Piranga rubra*)] are considered to be special-concern species under the LCR MSCP. The Yellow-breasted Chat (*Icteria virens*) is also considered a special concern species in California. We did not survey specifically for these species but recorded all incidental detections.

METHODS

Site Selection

Survey sites were selected based on locations surveyed during previous years of willow flycatcher studies on the lower Colorado River (McKernan 1997; McKernan and Braden 1998, 1999, 2001a, 2001b, 2002; McLeod et al. 2008a) and reconnaissance by helicopter, by boat, and on foot prior to the start of the 2008 survey period. Sites consisting of mature native or exotic woody riparian vegetation with high canopy closure (>50%) and standing water or saturated soil under or adjacent to the vegetation were considered the most suitable habitats for flycatchers. Early successional stands of young riparian vegetation >3 m in height in proximity to surface water or saturated soil were also considered suitable flycatcher habitat. Riparian vegetation contiguous with suitable habitat was often included as part of survey areas. Reclamation biologist Theresa Olson guided and approved site selection. For sites surveyed in previous years, we retained original site names.

In 2008 we implemented a biennial survey schedule at selected sites in study areas where resident flycatchers have not been documented in the last 10 years of surveys. Sites were selected for biennial surveys based on the absence of damp or wet soils within the site and/or the relative absence of dense vegetation that might provide suitable nesting habitat for flycatchers (Table 2.1). The survey schedule is subject to revision based on conditions observed during the 2008 survey season and in future years.

Table 2.1. Proposed Survey Schedule for Sites Where No Resident Flycatchers Have Been Detected since 1996

Study Area[1]	Site	Habitat Comments	Proposed Survey Schedule		
			Annual	2008, 2010, 2012	2009, 2011
TOGO	Pulpit Rock	Tiny. Wet soil adjacent to river; upland edge dry.			X
	Picture Rock	Wet soil adjacent to river, interior dry.			X
	Blankenship Bend North	Stand of Goodding willow adjacent to marsh.	X		
	Blankenship Bend South	Mosaic of cattail, bulrush, willow. Areas with water under vegetation.	X		
	Havasu NE	Mature vegetation; most of interior of site is very dry, willows near lakeshore – need to evaluate soil conditions in area with willows. Annual survey unless evaluation reveals no suitable habitat.	X		
BIHO	Big Hole Slough	Marshy, new willows coming in.	X		
EHRE	Ehrenberg	Decent structure; needs more water.	X		

Table 2.1. Proposed Survey Schedule for Sites Where No Resident Flycatchers Have Been Detected since 1996 (Continued)

Study Area[1]	Site	Habitat Comments	Proposed Survey Schedule		
			Annual	2008, 2010, 2012	2009, 2011
CIBO	CVCA	New restoration area.	X		
	Cibola Nature Trail	Generally dry and sparse, restoration area. Habitat improvements taking place, may improve.	X		
	Cibola Island	Only surveyed in 2007, need to evaluate. Annual schedule, pending results of evaluation.	X		
	Cibola Site 2	No dense canopy. Mostly tamarisk with some emergent willow. Cattail marshes in parts of the site, but dry soil under the tamarisk.			X
	Cibola Site 1	No dense canopy. Mostly tamarisk with some emergent willow. Cattail marshes in parts of the site, but dry soil under the tamarisk.			X
	Hart Mine Marsh	Mostly tamarisk, with linear stretches of marsh vegetation. Dry soil under the tamarisk.			X
	Three Fingers Lake	Very dry and hot in interior, vegetation short.		X	
	Cibola Lake #1 (North)	Patchy vegetation, hot and dry in interior.		X	
	Cibola Lake #2 (East)	Patchy vegetation, hot and dry in interior.			X
	Cibola Lake #3 (West)	Patchy vegetation, hot and dry in interior.		X	
	Walker Lake	Large willows and water under vegetation along lake edge.	X		
IMPE	Draper Lake	Recovering from fire. Need to evaluate. Annual survey, pending results of evaluation.	X		
	Paradise	Some big willows with tamarisk understory, sometimes has water in marshes.	X		
	Hoge Ranch	Mosaic of tamarisk, willow, and marshes. Sometimes wet.	X		
	Adobe Lake	Perched above river, very dry, dense tamarisk with many dead branches in understory.		X	
	Rattlesnake	Dense willows, wet soils.	X		
	Norton South	Very small, old plantation. Sometimes contains water.			X
	Milemarker 65	Very narrow strip (<50m) of tamarisk adjacent to bulrush marsh. Understory of ***Phragmites*** creates extremely dense vegetation within 3 m of ground.			X
	Clear Lake/The Alley	Mature tamarisk, very dense understory. Very dry except immediately next to backwater channel.		X	
	Nursery NW	Dense tamarisk interspersed with marsh areas.	X		
	Imperial Nursery	Plantation. No understory.		X	
	Ferguson Lake	Mix of willow and tamarisk with water under vegetation on west side of site. East side is dry and scrubby.	X		

Table 2.1. Proposed Survey Schedule for Sites Where No Resident Flycatchers Have Been Detected since 1996 (Continued)

Study Area[1]	Site	Habitat Comments	Proposed Survey Schedule		
			Annual	2008, 2010, 2012	2009, 2011
IMPE	Ferguson Wash	Mature tamarisk with emergent willow. Very dry in interior of site. Borders backwater channel and Ferguson Lake. Need to determine whether there are any moist soils under the mature vegetation. Annual survey pending results of evaluation.	X		
	Great Blue Heron	Good structure, moist soils.	X		
	Powerline	Very small, stringer of trees around cattail marsh that sometimes contains water. Sparse canopy.			X
	Martinez Lake	Scattered willows, tamarisk and arrowweed understory, sparse canopy closure.			X
MITT	Mittry West	Willow overstory, tamarisk understory, 80% canopy closure, sometimes wet.	X		
	Mittry South	Monotypic tamarisk, lots of deadfall. Interior is dry. Adjacent to lake.		X	
YUMA	Gila Confluence North	Patchy. A few small stands of mature willows around cattail marshes. Marshes sometimes contain water. Half of site burned in 2006. Overall canopy closure 50%.		X	
	Gila River Site #1	Recovering from fire. Still very sparse.			X
	Gila River Site #2	Cottonwood/willow overstory, tamarisk and arrowweed understory, dry soils in interior, canopy closure 50%.			X
	Fortuna Site #1	Narrow (30m) strip of cottonwood/willow. Patchy understory of tamarisk and arrowweed on periphery, no understory within cottonwood/willow. Interior is dry.			X
	Fortuna North	Mature tamarisk, 80% canopy closure. Interior very dry. Adjacent to Gila River.			X
	Morelos Dam	Recovering from fire, canopy closure less than 50%, widely spaced willow and cottonwood, dense patch of tamarisk on northern end of site.			X

[1] TOGO = Topock Gorge, BIHO = Big Hole Slough, EHRE = Ehrenberg, CIBO = Cibola NWR, IMPE = Imperial NWR, MITT = Mittry Lake, YUMA = Yuma.

We provided field personnel with high-resolution aerial photographs of all selected survey sites. The photographs were overlain with a UTM grid (NAD 83) and an outline of the proposed survey area. The boundaries of all survey sites were refined to include potential flycatcher habitat actually present. New boundaries were delineated on the aerial photographs based on UTM coordinates obtained in the field. All UTM coordinates were obtained using a Garmin Rino 110 GPS unit and were in NAD 83 to comply with Federal Geographic Data Committee standards.

Additional Site Evaluation

During the survey season, we conducted on-the-ground habitat reconnaissance and evaluation to locate additional potentially suitable willow flycatcher habitat and to reevaluate areas we had visited in previous years and had noted as potentially suitable. Field personnel were provided high-resolution aerial

photographs overlain with a UTM grid to aide with navigation and the identification of potentially suitable flycatcher habitat. We focused habitat reconnaissance and evaluation in areas that contained or were adjacent to standing water or saturated soils, and that had vegetation characteristics similar to that of flycatcher breeding sites (i.e., dense vegetation within 2–4 m of the ground and high canopy closure). Broadcast surveys were conducted opportunistically during ground reconnaissance. Field personnel formulated qualitative site descriptions of all evaluated areas.

Broadcast Surveys

To elicit responses from nearby willow flycatchers, we broadcast conspecific vocalizations previously recorded throughout the Southwest from 1996 to 1998. All flycatcher surveys were conducted according to methods described in Sogge et al. (1997), and we followed a 5-survey protocol, as recommended by the U.S. Fish and Wildlife Service (USFWS 2000). We completed at least one survey between 15 and 31 May, at least one survey between 1 and 15 June, and three additional surveys between 16 June and 25 July. Surveys were separated by a minimum of five days whenever logistically possible. Field personnel surveyed within the habitat wherever possible, using a portable CD or MP3 player (various models were used) coupled to a Radio Shack 277-1008C mini amplified speaker. Surveyors stopped every 30–40 m and broadcast willow flycatcher primary song (***fitz-bew***) and calls (***breets***). Field personnel watched for flycatchers and listened for vocal responses for approximately one to two minutes before proceeding to the next survey station. Wherever territorial flycatchers were detected, broadcast surveys were discontinued within a radius of 50 m of territories, and territory and nest monitoring commenced (see Chapter 4). If a willow flycatcher was observed but did not respond with song to the initial broadcast, we broadcast other conspecific vocalizations including ***creets/breets***, ***wee-oos***, ***whitts***, ***churr/kitters***, and a set of interaction calls given by a mated pair of flycatchers (per Lynn et al. 2003). These calls were frequently effective in eliciting a ***fitz-bew*** song, thereby enabling surveyors to positively identify willow flycatchers. To produce a spatial representation of all survey areas, field personnel recorded survey start and stop UTM coordinates as well as the UTM coordinates of intermediate survey points. Observers recorded start and stop times and the location(s) and behavior of all willow flycatchers detected (see survey form, Appendix A). Field personnel also recorded the presence of Brown-headed Cowbirds (hereafter cowbirds) and livestock, as requested by the Arizona Game and Fish Department. Cowbirds may affect flycatcher populations by decreasing flycatcher productivity (see Chapter 4), while livestock may substantially alter the vegetation in an area (USFWS 2002).

Site Description

Because vegetation structure and hydrology within riparian habitats are seasonally dynamic, field personnel completed site description forms (Appendix A) for each survey site at least three times throughout the survey season: early season (mid-May), mid-season (mid-June), and late season (mid-July). Vegetation composition (native vs. exotic) at survey sites followed the definitions of Sogge et al. (1997) and the Southwestern Willow Flycatcher Range-wide Database. Vegetation composition was defined as (1) native: >90% of the vegetation at a site was native; (2) exotic: >90% of the vegetation at a site was exotic/introduced; (3) mixed-native: 50 to 90% of the vegetation at a site was native; or (4) mixed-exotic: 50 to 90% of the vegetation at a site was exotic/introduced. Information from site description forms was used in conjunction with habitat photographs and comments in field notebooks and on survey forms to formulate qualitative site descriptions.

RESULTS

Field personnel spent 680.7 observer-hours conducting willow flycatcher broadcast surveys at 77 sites along the Virgin and lower Colorado Rivers and tributaries.[3] Willow flycatcher survey results are summarized in Table 2.2 and are presented below along with site descriptions. The boundaries of survey sites and occupancy in 2008 are shown on orthophotos in Appendix B, along with historically occupied habitat.[4] Each site that was not occupied by territorial flycatchers was formally surveyed between four and six times. Field personnel spent an additional 53.9 observer-hours completing habitat reconnaissance and evaluation and opportunistic surveys. The results of reconnaissance for each study area are presented below following the results for the regularly surveyed sites. Because subspecies identification of willow flycatchers detected between approximately 15 June and 20 July in the breeding range of ***E. t. extimus*** is problematic (Sogge et al. 1997, USFWS 2002), flycatcher detections after 15 June at sites where breeding or residency was not confirmed are summarized in Table 2.3. Yellow-billed Cuckoo and Yuma Clapper Rail detections are listed in Tables 2.4 and 2.5, respectively, and overall numbers of detections of all special concern species are listed in Appendix C. Hydrologic characteristics of each site are summarized in Table 2.6.

Table 2.2. Willow Flycatcher Detections at Survey Sites along the Virgin and Colorado Rivers and Tributaries, 2008*

Study Area[1]	Survey Site	Area (ha)	Number Detected (Date(s) of Detection)[2,3]
PAHR	North	4.6	26 (14 May–12 Aug)

	Overton WMA	14.9	10 (11 May–11 Aug)

[3] We started the survey season with 76 sites scheduled for surveys in 2008. We discontinued surveys at three sites because of poor habitat quality and added one site mid-season as the result of habitat reconnaissance.

[4] As per Reclamation (1999), we defined occupied Southwestern Willow Flycatcher habitat as patches of vegetation that are similar to and contiguous with areas where willow flycatchers were detected after 15 June.

* Values are given for each site as recorded in mid-May, mid-June, and mid-July.

[1] PAHR = Pahranagat NWR, LIFI = Littlefield, MESQ = Mesquite West, MOME = Mormon Mesa, MUDD = Muddy River, GRCA = Grand Canyon, TOPO = Topock Marsh, TOGO = Topock Gorge, AHAK = Ahakhav Tribal Preserve, BIWI = Bill Williams River NWR, BIHO = Big Hole Slough, EHRE = Ehrenberg, CIBO = Cibola NWR, IMPE = Imperial NWR, MITT = Mittry Lake, YUMA = Yuma.

[2] -- = Hydrologic information not recorded.

[3] Percent of site with saturated soil does not include inundated areas.

[4] Site bordered by a river, lake, or pond.

[5] The amount of surface water present within the site varies daily and throughout the survey season; hydrology at the site is influenced by irrigation runoff from two golf courses immediately adjacent to the site.

[6] The deepest water occurred within a channel of the Muddy River that runs through the center of the site.

[7] Saturated soil or water was present in pig wallows.

[8] Site borders marsh.

[9] Site is irrigated as part of restoration efforts; amount of standing water highly variable throughout survey season.

Pahranagat National Wildlife Refuge, Nevada

Pahranagat National Wildlife Refuge consists of a series of lakes and marshes in Pahranagat Valley approximately 150 km north of Las Vegas, Nevada. Patches of primarily native vegetation exist at the

inflow and outflow of Upper Pahranagat Lake. Prior to the 2008 survey season, the majority of the riparian vegetation along the north side of the upper lake (Pahranagat North) was inundated annually with up to 1 m of water, with the highest water levels occurring in May. Major structural problems with the levee that impounds the upper lake resulted in the upper lake being drained in early 2008, and the riparian vegetation at the north end of the lake was not flooded during the 2008 breeding season as it had been in previous years.

Pahranagat North

Area: 4.6 ha Elevation: 1,026 m

Pahranagat North is a stand of large-diameter Goodding willow (*Salix gooddingii*) at the inflow of Upper Pahranagat Lake. Fremont cottonwood (*Populus fremontii*; hereafter cottonwood) lines the northern, upland edge of the site and extends in narrow stringers around the edge of the lakebed. Canopy height within the patch is 15–18 m, and canopy closure is approximately 70%. During the survey season, standing water and saturated soils were present only in an inflow channel that runs along the northern side of the site and drains into the lakebed at the southeastern corner of the site. The water channel is vegetated with bulrush (*Schoenoplectus californicus*) where it enters the lakebed. Saturated soils were also present within patches of bulrush that border the southern edges of the site.

We detected 16 breeding willow flycatchers, as well as 8 resident, unpaired males. In addition to resident adults, we detected two individuals for which residency and/or breeding status could not be confirmed. Details of occupancy, pairing, color-banding, and breeding are presented in Chapters 3 and 4. Areas of Pahranagat North not known to be occupied by willow flycatchers were surveyed five times, totaling 6.9 observer-hours. The site lies immediately adjacent to a cattle pasture, but livestock have access only to the cottonwood stringer on the northwestern corner of the lake, which is separated from the survey site by a fence. Individual cows made incursions into the site on two known occasions but were removed within 24 hours. Cowbirds were detected during one survey.

Pahranagat West

Area: 1.5 ha Elevation: 1,026 m

This native site consists of a stringer of cottonwood, one to three trees wide and 20 m in height, on the western edge of Upper Pahranagat Lake. A few Goodding willow 2–4 m in height are also present, but the site has no significant understory vegetation. The eastern edge of the site is vegetated with bulrush, which extends into the lakebed to the east. During the survey season, the upland edge of the site was dry, while the bulrush along the lakebed edge had saturated soils until mid-June.

We detected no willow flycatchers. We surveyed the site five times, totaling 2.8 observer-hours. Cowbirds were detected on one survey, and there was no sign of livestock use.

Pahranagat MAPS

Area: 2.7 ha Elevation: 1,026 m

Pahranagat MAPS is a stringer of cottonwood on the western edge of the bed of Upper Pahranagat Lake. Canopy height is 15–20 m, and canopy closure is approximately 60%. There is no woody vegetation in the understory, and cattail (*Typha* sp.) and bulrush line the eastern edge of the tree line. The site was dry

throughout the survey season, with the nearest water or saturated soil being at least 25 m away in the lakebed.

No willow flycatchers were detected. We surveyed the site five times, totaling 4.8 observer-hours. No cowbirds were detected and there was no evidence of livestock use.

Pahranagat South

Area: 2.5 ha Elevation: 1,023 m

Pahranagat South consists of a relatively small stringer of Goodding willow, coyote willow (*Salix exigua*), and cottonwood lining a human-made channel that carries the outflow from Upper Pahranagat Lake. The cottonwoods reach approximately 20 m in height, while the willows are generally less than 10 m. In 2005, we noted that dense coyote willow was increasing on the western side of the patch; this area of willow had very sparse canopy in 2006 and 2007, and the coyote willow was almost completely dead in 2008. The site is bordered to the west by an open marsh and to the east by upland scrub. Tamarisk (*Tamarix* spp.) and Russian olive (*Elaeagnus angustifolia*) form a sparse understory. Overall canopy closure at this site is approximately 50%. The channel held varying amounts of water throughout the survey season.

We did not detect any willow flycatchers. We surveyed the site seven times, totaling 4.0 observer-hours. Cowbirds were detected during one survey, and no sign of livestock was observed.

Littlefield, Arizona

In 2007, our survey and monitoring activities focused on an area along Beaver Dam Wash immediately upstream of the Highway 91 Bridge. We expanded the survey area in 2008 to include young Goodding and coyote willow stringers downstream of the bridge.

Littlefield Poles

Area: 2.6 ha Elevation: 565 m

Littlefield Poles consists of two relatively small patches of mixed-native vegetation located on Beaver Dam Wash, immediately upstream and downstream of the Highway 91 Bridge. Vegetation upstream of the bridge consists of a scattered overstory of cottonwood averaging 25 m in height. Cottonwood and Goodding willow averaging 10 m in height are present below the overstory but do not form a continuous canopy. Lower strata vegetation approximately 6 m in height consists of coyote willow, tamarisk, and some Russian olive. Cattail is present along the southern edge of the patch, and the vegetation is bordered to the south by a stream. Downstream of the bridge, young stringers of Goodding and coyote willow reach 5 m in height and form linear patches 10–15 m wide on the edges of multiple stream channels. Larger Goodding willow is present on the edge of the golf course that borders the southwestern edge of the site. Canopy closure in the densest areas of Goodding and coyote willow is >90%, though overall canopy closure ranges from 50 to 70%. Surface water was present in stream channels throughout the survey season.

We detected one willow flycatcher for which residency could not be confirmed. Three subsequent territory monitoring visits failed to detect the flycatcher again. Details of occupancy and color-banding are presented in Chapter 3. We surveyed Littlefield Poles five times, totaling 5.5 observer-hours. Cowbirds were detected on all surveys. Cattle were observed in the site on two occasions, and cattle scat and trails were observed on all visits.

Mesquite, Nevada

The Mesquite study area is in the floodplain of the Virgin River near Mesquite and Bunkerville, Nevada. The entire area experience flooding, and some areas were scoured, during the 2004–2005 winter floods.

Mesquite East

Area: 4.4 ha Elevation: 468 m

This mixed-native site lies on several terraces within the floodplain of the Virgin River in Mesquite, Nevada. Vegetation on the lowest terrace, on the northern edge of the site adjacent to the river, consists of cottonwood and Goodding willow generally less than 10 m in height. The central portion of the site lies on a slightly higher terrace and is vegetated entirely by dense tamarisk 7–8 m in height with canopy closure around 80%. The uppermost terrace is vegetated with Goodding willow and a few cottonwood 18–25 m in height and an understory of dense clumps of coyote willow about 8 m in height. Canopy closure on this terrace varies from 50% in the cottonwood/Goodding willow areas to over 90% in the coyote willow clumps. The western half of the upper terrace burned over the 2004–2005 winter and has grown back with thick stands of coyote willow and cottonwood. A small drainage pond at the end of an irrigation ditch held standing water throughout the survey season.

We detected one willow flycatcher. Three subsequent territory monitoring visits failed to detect the flycatcher again. Details of occupancy and color-banding information are presented in Chapter 3. We surveyed Mesquite East five times throughout the flycatcher breeding season, totaling 8.8 observer-hours. Cowbirds were detected on all but one survey, and cattle trails and scat were observed on all surveys.

Mesquite West

Area: 11.5 ha Elevation: 470 m

This mixed-native site lies within the floodplain of the Virgin River in Mesquite, Nevada. Golf courses and housing developments border the site to the north, and the Virgin River borders the site to the south. This large site is primarily a mosaic of cattail and bulrush marshes separated by narrow (40–50 m) strips of dense coyote willow with interspersed tamarisk. The coyote willows are generally 5 m in height, and canopy closure varies from 50 to >90%. Hydrology at the site is influenced by irrigation runoff from the two adjacent golf courses, and the amount of surface water present under the vegetation varied daily and throughout the season. The site contained standing water and muddy soils throughout the survey season, and the irrigation runoff supports much of the vegetation within the site.

We detected 21 breeding willow flycatchers and 3 resident, unpaired males. In addition to resident adults, we detected three individuals for which residency and/or breeding status could not be determined. Details of occupancy, pairing, color-banding, and breeding are presented in Chapters 3 and 4. Areas of Mesquite West not known to be occupied by flycatchers were surveyed five times throughout the flycatcher breeding season, totaling 23.2 observer-hours. Cowbirds were detected on all but one survey. Evidence of livestock was observed on the last three surveys, and cattle were observed on the banks of the Virgin River immediately adjacent to the southern edge of the site. Cattle were observed within the site on at least one territory monitoring visit.

Electric Avenue North

Area: 1.8 ha Elevation: 460 m

This mixed-exotic site lies adjacent to an agricultural field within the floodplain of the Virgin River in Bunkerville, Nevada. During the summer of 2007, an area running northwest to southeast was bulldozed through the center of the site, removing approximately 20% of the vegetation present in previous years and creating a drainage ditch. Vegetation at the site consists of an overstory of cottonwood, Goodding willow, and tall coyote willow averaging 10 m in height. Shorter coyote willow and tamarisk averaging 8 m in height make up the understory. Most of the willows are dead, and the cottonwoods have sparse leaves, creating canopy closure less than 50%. A cattail marsh on the northwestern edge of the site is lined with narrow (<5 m wide) stringers of young coyote willow. The vegetation around the marsh is not currently mature or extensive enough to provide flycatcher habitat but should be evaluated in future years. The marsh held surface water in May.

We did not detect any flycatchers at this site. We surveyed the site one time, totaling 1.5 observer-hours. Cowbirds were detected, and evidence of livestock use was observed. Surveys were discontinued because most of the vegetation at the site is dead.

Electric Avenue South

Area: 3.9 ha Elevation: 460 m

This mixed-exotic site lies adjacent to an agricultural field within the floodplain of the Virgin River in Bunkerville, Nevada. Vegetation at the site consists of a scattered overstory of cottonwood and Goodding willow averaging 12 m in height with a predominantly tamarisk understory. Some coyote willow is scattered throughout the site, and arrowweed (*Pluchea sericea*) and mesquite (*Prosopis* sp.) trees mix with the tamarisk in some areas. A cluster of cottonwood is located at the northern end of the site. The cottonwoods have sparse leaves, many of the willows are dead, and approximately 50% of the tamarisk understory is dead. Canopy closure is less than 50%. The interior of the site was dry in May, though water was present in a marshy area along the southeastern edge of the site. A high embankment prevents water in the marsh from flowing into the site.

We did not detect any flycatchers at this site. We surveyed the site one time, totaling 1.6 observer-hours. Cowbirds were detected, but no evidence of livestock use was observed. Surveys were discontinued because most of the vegetation at the site is dead.

Bunker Farm

Area: 1.9 ha Elevation: 457 m

This exotic site lies within the floodplain of the Virgin River in Bunkerville, Nevada, approximately 3 km downstream of Mesquite West. The site is between an agricultural field to the southeast and the Virgin River to the northwest. Most of the southwestern third of the site was bulldozed prior to the start of surveys in 2008. Vegetation at the site consists of tamarisk 4–7 m in height and of varying density, with canopy closure not exceeding 60%. Many of the emergent Goodding willow are dead or dying. The coyote willow that had formed dense stands within the site in previous years was completely dead in 2008. The site was dry throughout the survey season. This is the fourth consecutive year that the agricultural field adjacent to the site was fallow, and the site did not receive agricultural runoff.

We detected one willow flycatcher for which residency could not be confirmed. Three territory monitoring visits as well as three subsequent surveys failed to detect the flycatcher again. Details of occupancy and color-banding are presented in Chapter 3. Although initial visits to the site revealed that the vegetation is no longer suitable for resident flycatchers, we visited the site regularly as part of our microclimate studies (see Chapter 6) and continued to survey the site. We surveyed the site five times, totaling 8.0 observer-hours. Cowbirds were detected only on the first survey. Evidence of livestock use was observed on all visits.

Mormon Mesa, Nevada

For approximately 15 km upstream of its outflow to Lake Mead, the Virgin River flows through a 1-km-wide floodplain with a mosaic of habitats, including cattail marshes and tamarisk and willow forest. Much of the area is typically seasonally inundated from snowmelt in the spring and monsoon rains in mid and late summer, and the entire study area experienced severe flooding over the 2004–2005 winter. All the areas surveyed at Mormon Mesa are at least 10 km upstream of Lake Mead, though we did complete habitat reconnaissance along the Virgin River near its mouth at the Overton Arm of Lake Mead.

Mormon Mesa North

Area: 8.2 ha Elevation: 390 m

This mixed-exotic site consists primarily of tamarisk 3–5 m in height with areas of emergent Goodding willow. Overall canopy closure is around 50%. The willows in the central and eastern portions of the site are primarily dead, while the northern end of the site has clumps of live Goodding willow 10–12 m in height with a 3-m tamarisk understory. The western edge of the site has a 100 x 50 m patch of Goodding willow, 8 m in height, with up to 75% canopy closure and dead cattails in the understory. The center of the site consists of dead coyote willow and was not surveyed. No standing water or saturated soils were present within the site during the survey season. Surface water was adjacent to the site throughout the survey season in a marsh to the west and in the river channel to the south. The site is perched up to 2 m above the water level.

We did not detect any flycatchers. We surveyed the site six times, totaling 18.2 observer-hours. Cowbirds were detected on all surveys as was evidence of livestock use. Cattle were observed in or adjacent to the site on at least four occasions.

Hedgerow

Area: 1.1 ha Elevation: 390 m

This mixed-exotic site is east of Mormon Mesa North, on the eastern side of the Virgin River. The site consists of a continuous understory of tamarisk 4–5 m in height with scattered emergent Goodding willow up to 12 m in height. The site is surrounded by tamarisk and arrowweed 2–3 m in height. Canopy closure at the site varies from about 50% on the edges of the site up to 80% in the denser areas. Soils within the site were dry throughout the survey season.

We did not detect any flycatchers. We surveyed the site five times, totaling 3.9 observer-hours. Cowbirds were not observed, but evidence of cattle was observed on each visit.

Mormon Mesa South

North half: Area: 12.9 ha Elevation: 385 m
South half: Area: 7.0 ha Elevation: 385 m

This mixed-exotic site was split into two contiguous areas to facilitate tracking of survey activity. Mormon Mesa South consists of a mosaic of tamarisk 4 m in height and patches of Goodding willow up to 12 m in height. A long stringer of willow runs north to south through the site. Canopy height of the willows is up to 12 m. Canopy closure varies throughout the site, averaging around 70%. There was no surface water within the site, but damp soils were noted in May and June.

We detected two willow flycatchers. Subsequent visits, including three territory monitoring visits, yielded no further detections. Details of banding and occupancy are presented in Chapter 3. We surveyed the northern half of the site five times, totaling 23.3 hours. The southern half was also surveyed five times, for a total of 18.3 observer-hours. Cowbirds were detected on all but one survey. Evidence of livestock was documented on all visits, and cattle were observed in the site on several occasions.

Virgin River #1

North half: Area: 16.5 ha Elevation: 380 m
South half: Area: 24.9 ha Elevation: 380 m

Virgin River #1 was also divided into two areas, Virgin River #1 North and Virgin River #1 South, to facilitate streamlining of field logistics. Virgin River #1 North is primarily tamarisk 4–5 m in height with areas of emergent Goodding willow and patches of coyote willow. Canopy closure throughout the site is 50–70%. The emergent willows in the northeastern portion of the site, which supported breeding flycatchers in 2003 and 2004, are now completely dead and many have fallen. The soil in most of the site is sandy, though during the surveys the center of the site had areas of damp, slippery clay, and standing water was present on cattle trails early in the season. The southwestern corner of the site also contained surface water in May and June.

We detected one breeding pair of willow flycatchers in the southwestern corner of Virgin River #1 North. Details of occupancy, color-banding, and breeding are presented in Chapters 3 and 4. Areas of this site not known to be occupied by flycatchers were surveyed five times, totaling 37.3 observer-hours. Cowbirds were detected on all but one survey. Evidence of livestock and/or live cattle were observed on all visits.

Virgin River #1 South is primarily dense tamarisk approximately 4–5 m in height. The northwestern portion of the site is a marsh, where coyote and Goodding willows are interspersed with the tamarisk. Goodding and coyote willows in the site average 8 and 5 m in height, respectively. The southern third of the site consists of dense tamarisk with a few emergent Goodding willows, while the middle third of the site consists of sparser tamarisk with dry, open areas. Canopy closure in vegetated areas is approximately 90%. Standing water was present through June both in the marsh and in a stream channel in the southern third of the site.

We detected 15 breeding willow flycatchers and 3 unpaired, resident males in the northwestern portion of Virgin River #1 South. One additional willow flycatcher was detected for which residency could not be confirmed. Details of occupancy, color-banding, and nesting are presented in Chapters 3 and 4. Areas of the site not known to be occupied by willow flycatchers were surveyed five times, totaling 38.8 observer-hours. Cowbirds were observed on all but one survey as were cattle and/or evidence of cattle.

Virgin River #2

Area: 36.9 ha Elevation: 380 m

This site is primarily a monotypic stand of tamarisk 6 m in height with 70–90% canopy closure. Patches of emergent Goodding willow up to 10 m in height are also present. Most of the willows occur in a clump halfway down the eastern edge of the site, with widely scattered willows extending to the southern end of the site. The site contained no surface water during the breeding season, though about 10% of the site contained damp soils. The Virgin River, about 10 m from the eastern edge of the site, had surface water in May and June.

We detected five breeding willow flycatchers and one unpaired, resident male. We also detected one individual for which residency was not confirmed. Details of occupancy, color-banding, and nesting are presented in Chapters 3 and 4. Portions of the site not known to be occupied by flycatchers were surveyed five times, totaling 35.3 observer-hours. Cowbirds were observed on all surveys as were live cattle and/or evidence of cattle.

Ground Reconnaissance Results

"STILLWATER FLAT"

We explored this mixed-exotic area, northwest of Mormon Mesa North, because emergent willows were visible from the bluff overlooking the floodplain. The area is primarily sparse tamarisk 4 m in height with a few emergent Goodding willow up to 10 m in height. The southeastern corner of the site contains a few willows 3 m in height and dense tamarisk. Overall canopy closure is <50%, and soils throughout the site were very dry. Because vegetation was generally sparse and soils were dry, this area does not represent suitable flycatcher habitat and we do not recommend surveying it in future years.

No willow flycatchers were observed. The site was surveyed once, totaling 11.5 observer-hours. No cowbirds were detected, but evidence of livestock use was observed.

"RIVER MILE 30"

This mixed-exotic area is along the Virgin River approximately 5 km upstream of the confluence of the Virgin River and the Overton Arm of Lake Mead (Figure 2.2). We had not noted this area during helicopter reconnaissance, but aerial photographs taken after the 2004–2005 winter flood showed side channels bisecting dense vegetation. The area consists of tamarisk 3 m in height and arrowweed 2 m in height, and canopy closure is <50%. The only water present during the site visit in early June was in the main channel of the Virgin River. All vegetated areas were perched approximately 2 m above the riverbed, and the side channels that contained water at the time the aerial photograph was taken were dry and sandy. The vegetation is too short and dry to provide suitable flycatcher habitat, and we do not recommend surveys of this area in future years.

"VIRGIN NARROWS NORTH"

This native area is on the Virgin River approximately 3 km upstream of the confluence of the Virgin River and the Overton Arm of Lake Mead (Figure 2.2). We noted this area during helicopter reconnaissance in April 2008. It consists of a band of Goodding willow approximately 30 m wide and 100 m long paralleling the river on a dry terrace 1–1.5 m above the water. The willows are 4–6 m in height and are densest close to the river, becoming mixed with arrowweed away from the river. Foliage on the willows is not very dense, and canopy closure is 70–90%. Of the areas explored at Mormon Mesa,

this one most closely resembled suitable flycatcher habitat, though the vegetation was too sparse and the soils too dry to warrant further surveys. Given that the site is perched well above the water table, habitat conditions in the area seem unlikely to improve in future years. We do not recommend surveys of this area in future years.

"VIRGIN NARROWS EAST"

This mixed-native area is on the Virgin River approximately 2.8 km upstream of the confluence of the Virgin River and the Overton Arm of Lake Mead (Figure 2.2). We noted this area during helicopter reconnaissance in April 2008. The area consists of a series of dry terraces adjacent to the river, with the lowest terrace perched approximately 2 m above the riverbed. Vegetation consists primarily of a mix of arrowweed and tamarisk 3 m in height with scattered clumps and bands of emergent Goodding willow. Canopy closure is <50%. The site is too dry and sparsely vegetated to provide suitable flycatcher habitat, and we do not recommend surveys of this area in future years.

"VIRGIN NARROWS WEST"

This mixed-native area is on the Virgin River approximately 2.5 km upstream of the confluence of the Virgin River and the Overton Arm of Lake Mead (Figure 2.2). We noted this area during helicopter reconnaissance in April 2008. Vegetation consists of a 10-m-wide band of Goodding willow, approximately 8 m in height, on a narrow terrace perched 2 m above the riverbed. Arrowweed forms an understory 2 m in height. Leaves on the willows are sparse, and overall canopy closure is 70–90%. This area has the vegetation structure of suitable flycatcher habitat but lacks the foliage density, areal extent, and damp soils typical of flycatcher habitat. We do not recommend surveys in future years.

Muddy River, Nevada

The Muddy River study area is along the Muddy River in the Overton Wildlife Management Area (WMA) near Overton, NV.

Overton WMA Pond

Area: 0.7 ha Elevation: 378 m

This site consists of a patch of mixed-native vegetation approximately 150 m long and 150 m wide at the north end of Overton WMA just south of Honeybee Reservoir. The dominant vegetation consists of 10-m-tall Goodding willow with a sparse 5-m-tall tamarisk understory. Cattail and sedges are also present on the edges of the site. Canopy closure is variable, ranging up to 90%. A small stream channel runs through the site, and it held surface water in May and June. The marshy edges of the site had standing water throughout the survey season.

We detected one willow flycatcher. Three territory monitoring visits as well as subsequent surveys failed to detect the individual again. Details of occupancy and banding are presented in Chapter 3. Overton WMA Pond was surveyed six times for a total of 5.1 observer-hours. Cowbirds were detected at the site on all but one survey. No sign of livestock use was observed.

Overton WMA

Area: 14.9 ha Elevation: 378 m

This site consists of a 150-m-wide strip of riparian vegetation spanning both sides of the Muddy River. The site is bordered to the southwest by open agricultural fields and to the northeast by sparser areas of riparian vegetation. The site flooded heavily during the 2004–2005 winter, but vegetation at the site was relatively unchanged. The northern portion of the site is dominated by very dense tamarisk up to 7 m in height with canopy closure of 70–90%. The southern portion of the site consists primarily of a stand of Goodding willow 10–12 m in height with an understory of tamarisk and cattail and canopy closure up to 90%. Flowing water was present in the channel of the Muddy River throughout the survey season, and extensive beaver activity resulted in the southern portion of the site being flooded with approximately 30 cm of water throughout the survey season. Approximately 0.3 ha of the southern portion of the site was bulldozed in 2005 as part of Overton WMA efforts to repair flood damage to their water control system. Two stretches of the channel of the Muddy River within the site were dredged with heavy equipment over the 2007–2008 winter, resulting in a cleared swath 10–15 m wide on the western bank of the river. The more upstream of the two dredged and cleared areas extended from the northern end of the site southward for approximately 350 m, ending approximately 10 m upstream of the most upstream flycatcher nest recorded in 2005–2007. Dredging resumed less than 5 m downstream of the most downstream nest in that portion of the site and continued southwest along the river channel for approximately 400 m, ending over 100 m from the flycatcher nesting area at the southern end of the site.

We located six breeding willow flycatchers and two unpaired, resident males. We also detected two males for which residency could not be confirmed. Details of occupancy, color-banding, and nesting are presented in Chapters 3 and 4. Portions of the site not known to be occupied by flycatchers were surveyed five times, totaling 26.3 observer-hours. We observed no signs of livestock but detected cowbirds on all surveys.

Grand Canyon, Arizona

The Colorado River in lower Grand Canyon downstream of Separation Canyon is strongly influenced by water levels in Lake Mead. Potential willow flycatcher habitat in this area has changed dramatically in the last eight years as the result of a 33.8-m drop in the level of Lake Mead from 2000 to July 2008.[5] Much of the riparian vegetation in lower Grand Canyon from approximately RM 259.5 to RM 274 that was inundated and potentially suitable for flycatchers in the late 1990s is now terraced well above the current river level, and the existing vegetation in most of these areas is dead or unsuitable for flycatchers. New areas of willow and tamarisk developed along the Colorado River in Lake Mead National Recreation Area on newly exposed sediments over the last several years, and the vegetation in many of these areas subsequently died as the lake continued to drop.

Site names below indicate historical names (if applicable) and the river mile, as measured downstream from Lees Ferry. River left and river right are indicated by “S” (south) and “N” (north), respectively.

[5] The water level in Lake Mead Reservoir rose approximately 7 m from mid-2004 to early 2005 because of record precipitation during the winter of 2004–2005. Since mid-2005, the water level has continued to drop.

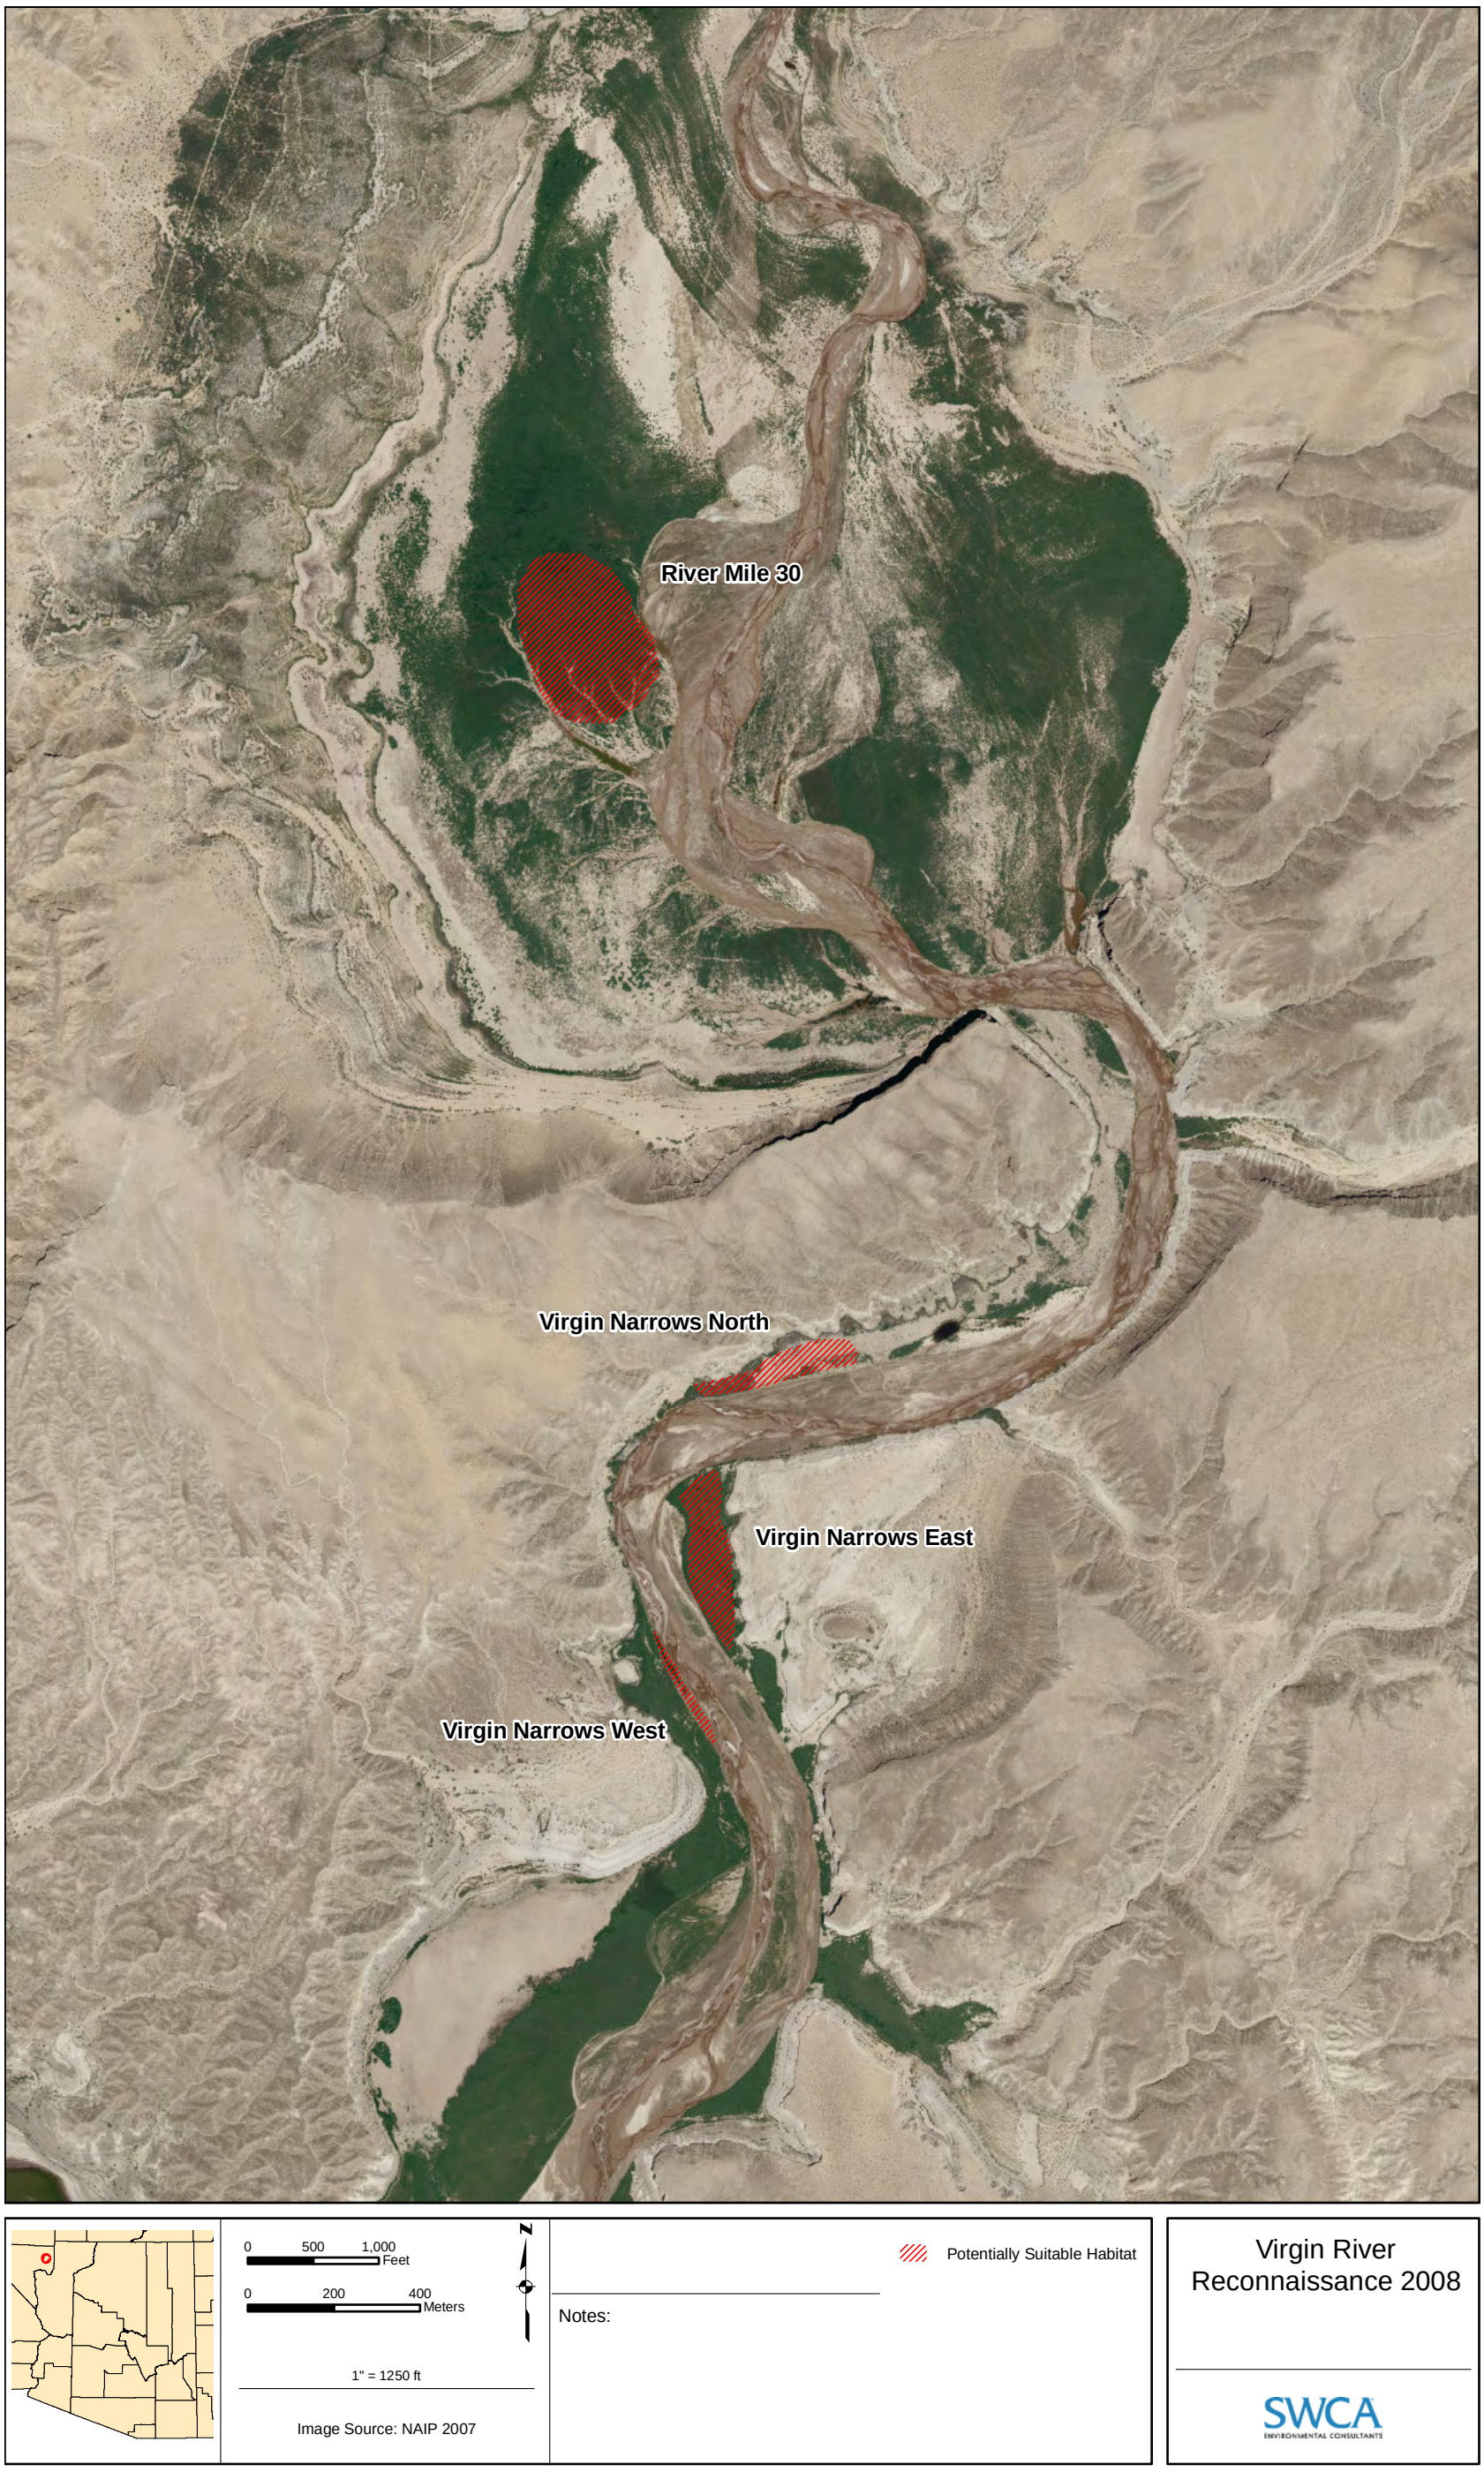

Figure 2.2. Reconnaissance areas near the mouth of the Virgin River, 2008.

Burnt Springs (RM 259.5N)

Area: 11.0 ha Elevation: 363 m

Vegetation within the first 200 m of Burnt Springs Canyon upstream from the Colorado River consists of extremely dense monotypic tamarisk approximately 5 m in height. The next 150 m of the canyon is vegetated by smaller tamarisk 3–4 m in height. This is followed by an approximately 700-m stretch of mature Goodding willow 15 m in height with an understory of cattails. Canopy closure is approximately 70–90%. Water was present in the streambed in the downstream half of the site through June.

We detected no willow flycatchers. We surveyed this site four times, totaling 3.5 observer-hours. Cowbirds were detected during two surveys, and no sign of livestock use was recorded.

RM 274.5N

Area: 18.3 ha Elevation: 354 m

This mixed-native site lies immediately adjacent to the Colorado River and contains several perennial springs, which feed small creeks, flooded willow and tamarisk forest, beaver ponds, and cattail marshes. Perennial creeks lined with coyote and Goodding willow connect the wetlands to the Colorado River. Throughout the survey season, deep pools of clear, standing water were present at springs, and large areas of the site contained muddy soils and standing water. Although the site has contained large areas of standing water since 2003, continued beaver activity has expanded the areas of standing water in the site compared to previous years. Vegetation at the site is a mosaic of well developed, mature Goodding willow forest, willow forest with tamarisk understory, and cattail marsh. Some cottonwoods are also present. Canopy height of the tamarisk is around 5 m, while the willows reach approximately 10 m. Canopy height and relative proportions of willow and tamarisk vary throughout the site. Canopy closure is highly variable but averages approximately 70%.

We detected no willow flycatchers. We surveyed this site four times, totaling 13.5 observer-hours. Cowbirds were detected on two surveys, and no sign of livestock use was observed.

RM 285.3N

Area: 8.6 ha Elevation: 343 m

This mixed-exotic site lies between the Colorado River and Grand Wash Bay, which was isolated from the Colorado River when the water level dropped in Lake Mead. Goodding willow and tamarisk developed on newly exposed soils, but the willows died as water levels continued to drop. The site has a steep, high bank adjacent to the river and slopes downward toward the bay. New vegetation continues to develop on the edge of the bay as additional soils are exposed. In 2008, the only dense vegetation at the site consisted of 3–4-m-tall willows in a narrow band on the edge of Grand Wash Bay. Vegetation in the rest of the site consisted of tamarisk 3 m in height with patches of dead willows. Canopy closure ranged from 25 to 70%. No standing water was present under the vegetation during the survey season, and saturated soils were present only in areas immediately adjacent to Grand Wash Bay.

No willow flycatchers were detected. We surveyed this site four times, totaling 2.6 observer-hours. Cowbirds were detected on one survey, and no evidence of livestock use was observed.

Iceberg Canyon

Area: 3.1 ha Elevation: 340 m

This small, mixed-native site is on recently exposed sediments along the Colorado River at the mouth of Iceberg Canyon. The site contains several small cattail ponds surrounded by bulrush, dense stands of Goodding willow averaging 6 m in height, and 3–4-m-tall tamarisk. Canopy closure ranges from 50 to 70%. The ponds contained standing water in June but were nearly dry by early July.

We detected one resident, unpaired male. Details of occupancy and color-banding are presented in Chapter 3. The site was surveyed three times, totaling 5.0 observer-hours. Cowbirds were detected on one survey, and no sign of livestock use was observed.

Topock Marsh, Arizona

Topock Marsh lies within Havasu NWR and encompasses over 3,000 ha of open water, cattail and bulrush marsh, and riparian vegetation. A large expanse (over 2,000 ha) of riparian vegetation occupies the Colorado River floodplain between the Colorado River on the western edge of the floodplain and the open water of Topock Marsh on the eastern edge of the floodplain. The vegetation is primarily monotypic tamarisk with isolated patches of tall Goodding willow. Seasonally wet, low-lying areas are interspersed throughout the riparian area.

Pipes #1

Area: 5.2 ha Elevation: 140 m

This exotic site is bordered to the east by the refuge road and consists primarily of monotypic tamarisk 5–7 m in height. Arrowweed occurs in dense patches within 50 m of the refuge road. The tamarisk is densest within 100 m of the refuge road and becomes more open toward the western edge of the site. The northern edge of the site has the tallest canopy, and there is relatively little deadfall in this area compared to the rest of the site. The central and southern portions of the site have many dead stems and clusters of fallen trees. Canopy closure is 50–70%. The site contained no standing water during the survey season but did contain damp soils through June.

No willow flycatchers were detected. We surveyed the site five times, totaling 9.5 observer-hours. Cowbirds were detected on all surveys, and evidence of feral pigs was observed.

Pipes #3

Area: 5.7 ha Elevation: 140 m

This site is bordered to the east by the refuge road. Arrowweed occurs in dense patches within 50 m of the road. Most of the site is vegetated by tamarisk 4–6 m in height. The southeastern portion of the site has two large Goodding willows and open, marshy areas. Canopy closure generally exceeds 70%. Most of the site was inundated in May. The site progressively dried out through the season but still contained damp soils and small areas of standing water in July.

Two breeding willow flycatchers were detected at Pipes #3. Details of occupancy, color-banding, and nesting are presented in Chapters 3 and 4. Portions of Pipes #3 not known to be occupied by flycatchers were surveyed five times, totaling 6.0 observer-hours. Cowbirds were detected and on three surveys, and evidence of feral pigs was observed on all surveys.

The Wallows

Area: 0.4 ha Elevation: 140 m

The Wallows is located between Pipes #3 and PC6-1 and is primarily vegetated by tamarisk 5–6 m in height with emergent Goodding willow on the western side of the site. Overall canopy closure ranges from 50 to 70%. The northwestern edge of the site borders an open cattail marsh. The Wallows contained standing water and saturated soils throughout the survey season.

One willow flycatcher was detected for which residency was not confirmed. Details of occupancy and color-banding are presented in Chapter 3. The site was surveyed six times, totaling 1.8 hours. Evidence of feral pigs was observed on all surveys. Cowbirds were not detected.

PC6-1

Area: 4.8 ha Elevation: 140 m

PC6-1 is a mixed-exotic site consisting primarily of tamarisk 6–7 m in height, with a few patches of arrowweed and cattails present in the understory. A scattered overstory of Goodding willow approximately 10–15 m in height is present in the southwestern corner of the site. Arrowweed 1–2 m in height is present under the willow. A portion of the site within approximately 50 m of the refuge road contains thick stands of arrowweed. Canopy closure in the interior of the site is approximately 90%, while canopy closure on the periphery of the site near the refuge road is approximately 50%. PC6-1 contained standing water and saturated soils throughout the survey season, though the percentage of the site inundated declined from over 50% in May to 10% in July.

No willow flycatchers were detected. The site was surveyed six times, totaling 11.4 observer-hours. Evidence of feral pigs was found on all surveys as were cowbirds.

Pig Hole

Area: 2.4 ha Elevation: 140 m

Pig Hole consists of monotypic tamarisk 6–7 m in height, with canopy closure ranging from 70 to 90%. The northern edge of the site has smaller-diameter tamarisk, with many wispy branches, than the remainder of the site. Approximately 5% of the site consists of dense patches of arrowweed. Approximately 25% of the site had standing water in May, and another 50% of the site had saturated soils. By mid-July, the standing water had disappeared and only 5% of the site contained saturated soils.

No willow flycatchers were detected. The site was surveyed six times, totaling 4.8 observer-hours. Cowbirds were detected on all but one survey. Evidence of feral pigs was observed on all surveys.

In Between

Area: 7.7 ha Elevation: 140 m

In Between consists of approximately 50-m-wide linear patches of monotypic tamarisk separated by swampy areas. Canopy height is approximately 7 m, with the lowest 3 m of the stand generally lacking foliage, resulting in a relatively open understory. Canopy closure in the tamarisk areas is 70–90%. The western edge of the site borders an open marsh and contained standing water and damp soil throughout the survey season.

We located one unpaired, resident male at In Between. Details of occupancy and color-banding are presented in Chapter 3. Portions of In Between not known to be occupied by flycatchers were surveyed six times, totaling 11.5 observer-hours. Cowbirds were recorded on five surveys, and evidence of feral pigs was observed on all surveys.

800M

Area: 6.1 ha Elevation: 140 m

800M adjoins the western edge of In Between, and the eastern half of the site consists of an open marsh. The remainder of the site is vegetated by tamarisk 4–7 m in height. Canopy closure in the tamarisk stands varies between 70 and 90%. Standing water and/or saturated soil were present in and along small areas of marsh and in pig wallows through the survey season.

We did not detect any willow flycatchers. We surveyed the site six times, totaling 5.8 observer-hours. Cowbirds and evidence of feral pigs were observed on all surveys.

Pierced Egg

Area: 6.7 ha Elevation: 140 m

This mixed-exotic site borders the western edge of 800M and consists of dense tamarisk 7 m in height, with a scattered overstory of Goodding willow 15 m in height. Areas with willows tend to have a more open understory and contain patches of cattails. Overall canopy closure is approximately 80%. Standing water and saturated soils persisted in portions of the site throughout the season.

We located nine breeding willow flycatchers and three additional flycatchers for which occupancy could not be confirmed. Details of occupancy, color-banding, and nesting are presented in Chapters 3 and 4. We surveyed the site one time for a total of 2.25 observer-hours. Cowbirds and evidence of pigs were observed. After the initial survey, Pierced Egg was visited as part of territory monitoring.

Swine Paradise

Area: 2.4 ha Elevation: 140 m

This mixed-exotic site borders the open water of Topock Marsh. Near the marsh, vegetation at the site is dominated by Goodding willow up to 15 m in height, with some coyote willow and an understory of tamarisk. The remainder of the site, on both sides of the main refuge road, is vegetated by tamarisk 6–8 m in height. Overall canopy closure is approximately 80%. Standing water and saturated soils persisted throughout the season in a cattail marsh on the eastern edge of the site.

No willow flycatchers were detected. We surveyed the site five times, totaling 3.0 observer-hours. Cowbirds were detected on all visits as was evidence of use by pigs.

Barbed Wire

Area: 2.6 ha Elevation: 140 m

This site is contiguous with Swine Paradise. One large, emergent Goodding willow occurs at the site; otherwise, the site is vegetated by tamarisk 5–8 m in height and of varying density. The northeastern portion of the site contains taller stems, less dead wood in the understory, and fewer large canopy

openings than the southwestern portion of the site. Canopy closure is approximately 90%. Standing water was present in pig wallows in May.

No willow flycatchers were detected. We surveyed the site five times, totaling 4.5 observer-hours. Cowbirds were detected on three visits. Evidence of pig use was observed on all visits.

IRFB03 and IRFB04

IRFB03: Area: 1.0 ha Elevation: 140 m
IRFB04: Area: 1.5 ha Elevation: 140 m

These two contiguous sites are separated from the Barbed Wire site by a firebreak road. They are vegetated by a monotypic stand of tamarisk 7 m in height, which forms a dense canopy and relatively open understory. There is little deadfall, although many standing stems are dead, leaving dense areas of dead branches in the understory. Canopy closure is >90%. Soils within these sites were completely dry throughout the survey season. Soils within these sites have been completely dry throughout all survey seasons from 2003 to 2008, and the sites thus do not represent typical breeding habitat for flycatchers. Therefore, we recommend discontinuing surveys at these sites.

One willow flycatcher was detected at IRFB04 on 27 May. This individual was likely a migrant and was not detected on subsequent visits to the site. We surveyed these sites five times each, totaling 3.8 observer-hours. Cowbirds were detected on one survey at both sites. Evidence of pigs was observed on all surveys.

Platform

Area: 1.3 ha Elevation: 140 m

This site forms a narrow strip of vegetation between the main refuge road and the open marsh. Vegetation at the site consists of tamarisk 7 m in height with a few isolated, emergent Goodding willow. Overall canopy closure is approximately 80%. Bulrush and cattail line the eastern edge of the site adjacent to the marsh. Hydrologic conditions in the interior of the site were not recorded.

No willow flycatchers were detected. We surveyed the site five times, totaling 1.3 observer-hours. Cowbirds were not detected at this site, but evidence of pigs was observed on four surveys.

250M

Area: 2.3 ha Elevation: 140 m

This site lies between the main refuge road and the open marsh. Vegetation composition and structure varies with distance from the marsh. Closest to the refuge road the site is dominated by mesquite trees with an understory of arrowweed. The center of the site is dominated by tamarisk approximately 7 m in height. Closest to the marsh, the site contains patches of coyote willow and one large Goodding willow. Canopy closure within the site is approximately 70%. Small patches of saturated soil were present adjacent to the marsh throughout the flycatcher breeding season.

We detected one willow flycatcher on 18 June for which residency was not confirmed. The site was surveyed five times, totaling 4.0 observer-hours. Cowbirds were detected on three surveys, and we observed evidence of pigs on all surveys.

Hell Bird and Glory Hole

Hell Bird: Area: 3.7 ha Elevation: 140 m
Glory Hole: Area: 5.0 ha Elevation: 140 m

These contiguous mixed-exotic sites are located on an island separated from the main riparian area by a narrow, deep channel. Vegetation composition and structure are highly variable, with the survey areas vegetated primarily by a mosaic of tamarisk 6 m in height and Goodding willow 12 m in height. Canopy closure ranges from 50 to 90%. The survey areas are bordered on the west by a sand dune and on other sides by dense bulrush. Large swampy areas vegetated by cattail and bulrush are interspersed throughout the survey areas. Hell Bird and Glory Hole both contained standing water throughout the flycatcher breeding season.

No willow flycatchers were found at Hell Bird. We detected six breeding flycatchers and two unpaired, resident males at Glory Hole. Details of occupancy, color-banding, and nesting activity are presented in Chapters 3 and 4. Hell Bird was surveyed five times, totaling 5.5 observer-hours. Portions of Glory Hole not known to be occupied by flycatchers were surveyed twice, totaling 5.0 observer-hours. Cowbirds and evidence of pigs were observed on all surveys at both sites.

Beal Lake

Area: 13.9 ha Elevation: 140 m

This mixed-native restoration site consists of a mosaic of relatively young cottonwood, Goodding willow, coyote willow, and arrowweed, with some tamarisk and mesquite scattered throughout the site. Canopy height is highly variable and averages approximately 5 m; canopy closure is sparse, averaging 35%. The amount of standing water and saturated soil at the site is highly variable because it is flood irrigated.

We detected two willow flycatchers on 5 June and one on 11 June. These individuals likely were migrants and were not detected on subsequent visits to the site. We surveyed this site five times, totaling 5.0 observer-hours. Cowbirds were detected on two surveys, and evidence of pigs was observed on three visits.

Lost Slough

Area: 1.5 ha Elevation: 140 m

Lost Slough is located approximately 4 km south of Glory Hole and Hell Bird. The site runs north-south for approximately 250 m, and measures 100 m wide at the broadest point. There is a marshy area in the center of the site that runs southwest to northeast; a small area of bulrush is present in the marsh, along with stands of coyote willow 6 m in height. Vegetation around the marsh is composed mainly of 6- to 8-m-tall tamarisk with a few emergent Goodding willow and mesquite scattered throughout.

Arrowweed up to 2 m in height makes up the understory vegetation. Canopy closure at the site is variable, with open areas toward the edges of the site and over 70% closure in areas with thick vegetation. Some surface water and saturated soils were present throughout the survey season.

We did not detect any willow flycatchers. We surveyed Lost Slough five times, totaling 4.5 observer-hours. Cowbirds were detected during one survey, and evidence of pigs was observed on four visits.

Lost Pond

Area: 1.2 ha Elevation: 140 m

This mixed-exotic site is located approximately 700 m southeast of Lost Slough. The site is approximately 200 m long and 125 m wide, with a small pond at the southern end of the site. The edges of the pond are vegetated with a 30-m-wide border of cattail, bulrush, and sedges. The pond is surrounded by tamarisk 4 to 7 m in height. Canopy closure in the tamarisk is approximately 90%. The area surrounding the site consists of arrowweed, 3-m tamarisk, and screwbean mesquite (*Prosopis pubescens*). Water remained in the pond throughout the flycatcher breeding season, and saturated soils and water were present under the tamarisk on the northeastern side of the pond.

No willow flycatchers were detected. We surveyed the site five times, totaling 2.1 observer-hours. Cowbirds were detected during one survey, and pig trails were present in the site.

Lost Lake

Area: 3.3 ha Elevation: 140 m

This site lies approximately 850 m southeast of Lost Pond. It is a narrow (<100-m-wide) strip of riparian vegetation separated from the Colorado River to the southwest by a low ridge of barren sand dunes and bordered to the northeast by marshy areas. Lost Lake (a 200- × 500-m body of open water) is located northwest of the site. Vegetation at the site is variable. The northern edge of the site consists of an overstory of planted cottonwoods 10–15 m in height, with an understory of tamarisk 5 m in height, on the edge of a cattail marsh. South of the cottonwoods, the site is primarily tamarisk, 5–8 m in height, with small openings vegetated by arrowweed. In previous years, the southeastern end of the site was dominated by dense stands of coyote willow. These willows are now all dead, dramatically reducing the suitability of the site for breeding flycatchers. Overall canopy closure is approximately 80%. Areas adjacent to the marsh edges held some standing water through mid-June.

No willow flycatchers were detected. We surveyed the site five times, totaling 4.0 observer-hours. Cowbirds and evidence of pigs were detected on all surveys.

Ground Reconnaissance Results

"NW OF PIPES #1"

We explored the area immediately northwest of Pipes #1 to determine whether the tall, dense tamarisk with relatively little deadfall that is present at the north end of Pipes #1 extends outside the area we currently survey. We encountered extremely dense tamarisk 8 m in height mixed with arrowweed. Canopy closure at the site is >90%. Soils within the site were completely dry. We abandoned attempts to explore this area because the dense vegetation made access very difficult.

No willow flycatchers were detected. We surveyed the site one time, totaling 3.8 observer-hours. Cowbirds and evidence of pigs were detected.

Topock Gorge, Arizona and California

Between Topock Marsh and Lake Havasu, the Colorado River winds through Topock Gorge. Throughout the Gorge, the river is confined between steep cliffs and high bluffs, and little vegetation grows along the river. We surveyed backwater areas that support marsh and riparian vegetation.

Blankenship Bend

Blankenship Bend North: Area: 26.7 ha Elevation: 138 m
Blankenship Bend South: Area: 25.9 ha Elevation: 138 m

Blankenship Bend is a 2-km-long strip of riparian and marsh vegetation that lies along the eastern bank of the Colorado River adjacent to the Blankenship Valley. The eastern, upland edge of the site is vegetated by a 100-m-wide strip of mature tamarisk and mesquite. The northern half of the site contains a stand of large Goodding willows adjacent to a cattail marsh. Between the river and the strip of tamarisk, the southern half of the site consists of a mosaic of cattail, bulrush, and scattered islands of small willows and tamarisk. Canopy closure and height are highly variable throughout this mixed-exotic site. Because of the proximity to the Colorado River, both sites contained standing water and saturated soils throughout the survey season.

No willow flycatchers were detected at either site at Blankenship Bend. We surveyed each site five times, totaling 7.5 observer-hours at Blankenship Bend North and 5.8 observer-hours at Blankenship Bend South. Cowbirds were detected on four surveys at North and on three surveys at South. Evidence of feral pigs and burros was observed at both locations.

Havasu NE

Area: 12.6 ha Elevation: 136 m

This mixed-native site consists of a 1.3-km-long and <100-m-wide strip of riparian vegetation along the northeastern shore of Lake Havasu. Vegetation at the site grades from cattails along the lakeshore to Goodding willow and tamarisk in the center of the site and a mix of tamarisk and mesquite on the upland edge. Canopy closure is approximately 80%. Many Goodding willows at the site are mature and stand 5 m above the 10-m-tall tamarisk and mesquite. Soils in the interior of the site were extremely dry throughout the survey season, and water from the lake does not extend under the vegetation. Based on our determination that no moist soils exist beneath the vegetation, we recommend biennial surveys for this site.

We did not detect any willow flycatchers. We surveyed the site five times, totaling 8.0 observer-hours. Cowbirds were detected on all visits as was evidence of use by pigs.

Bill Williams River National Wildlife Refuge, Arizona

The Bill Williams River NWR contains the last expanse of native cottonwood-willow forest on the lower Colorado River. The refuge encompasses over 2,500 ha along the Bill Williams River upstream from its mouth at Lake Havasu and contains a mixture of native forest, stands of monotypic tamarisk, beaver ponds, and cattail marsh. Survey sites within Bill Williams are listed below from west to east, moving progressively farther upstream.

In addition to the regularly scheduled surveys, we revisited sites located in previous years that were determined to be potentially suitable flycatcher habitat. Results of this habitat evaluation and opportunistic surveys are presented below following the survey results.

Bill Williams Site #2

Area: 3.1 ha Elevation: 140 m

This mixed-native site has an overstory of large Goodding willow and cottonwood up to 15 m in height and an understory of tamarisk 5 m in height. Overall canopy closure is approximately 70%. The northern portion of the site contains open cattail marshes. These cattails were dead in 2008, and the site contains much dead, woody vegetation in the understory. The site is bordered on the southwest by a narrow channel of open water where an arm of Lake Havasu follows the channel of the Bill Williams River, and vegetation is densest near this channel. The site is separated from the channel by a steep, high bank. There was a small amount of standing water in the cattail marsh in June, but soils under the woody vegetation were complete dry throughout the survey season. Because of dry soils within the site and the presence of large quantities of deadfall, this site does not represent typical occupied flycatcher habitat, and no resident willow flycatchers have been detected at this site since 2003. We recommend biennial surveys unless floods occur that have the potential to alter the hydrology of the area.

No willow flycatchers were detected. We surveyed the site six times, totaling 4.0 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Bill Williams Site #11

Area: 6.3 ha Elevation: 140 m

This mixed-native site has an overstory of Goodding willow and cottonwood trees up to 20 m in height. Tamarisk ranging from 3 to 5 m in height is the dominant species in the understory, and the ground is covered by thick deadfall. Canopy closure is approximately 75%. Large areas of standing water are present within the survey site because an arm of Lake Havasu follows the channel of the Bill Williams River through the center of the site. However, soils under the vegetation were very dry during the survey season. Because of dry soils within the site and the presence of large quantities of deadfall, this site does not represent typical occupied flycatcher habitat, and no resident willow flycatchers have been detected at this site since 2003. We recommend biennial surveys unless floods occur that have the potential to alter the hydrology of the area.

No willow flycatchers were observed. We surveyed the site five times, totaling 4.3 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock was observed.

Bill Williams Site #4 and Site #3

Site #4: Area: 9.9 ha Elevation: 140 m
Site #3: Area: 9.5 ha Elevation: 140 m

These two sites are contiguous and together are known as Mosquito Flats. Vegetation is mixed-native, with an overstory of Goodding willow 15–20 m in height and patches of monotypic tamarisk up to 8 m in height. Patches of coyote willow are also present. Overall canopy closure is approximately 50%. Stands of cattails and marshy areas occupy approximately 10% of the sites. The understory in some areas is very open, and the ground in these areas is covered with herbaceous vegetation. Many large willows and cottonwoods have fallen over the past several years, leaving large gaps in the canopy and creating patches of thick, dead, fallen woody vegetation. Mosquito Flats had a network of small, flowing streams in May, but these had largely dried to damp soil by July with only small puddles remaining.

We detected one willow flycatcher in Site #4 for which residency was not confirmed. Seven breeding flycatchers were detected in Site #3. Details of color-banding, occupancy, and nesting are presented in Chapters 3 and 4. Portions of the sites not known to be occupied by flycatchers were visited five times, totaling 7.2 observer-hours at Site #4 and 11.9 observer-hours at Site #3. Cowbirds were detected on all visits to Mosquito Flats, and no evidence of livestock was observed.

Bill Williams Site #5

Area: 9.0 ha Elevation: 143 m

Site #5 is located on the eastern edge of the Bill Williams River floodplain and is bordered to the east by upland desert. The survey site was expanded in 2008 approximately 350 m upstream. Vegetation in the site is mixed-native, with Goodding willow and cottonwood 15 m in height in the overstory. The understory consists of tamarisk 7 m in height as well as some young Goodding willow and cottonwood. Ground cover in portions of the site consists of thick, dead, fallen woody vegetation. Canopy closure in the site is variable, averaging 70%. Soils under the vegetation were mostly dry, with a couple of small ponds and small marshy areas containing water through July.

No willow flycatchers were detected. We visited the site five times, totaling 10.8 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Mineral Wash Complex

Area: 18.8 ha Elevation: 162 m

This mixed-native site is approximately 3 km upstream of Site #5. The northern third of the site is a sparse mix of tamarisk, honey mesquite (*Prosopis glandulosa*), and arrowweed with a few emergent cottonwood. The remainder of the site has an overstory of cottonwood and Goodding willow up to 20 m in height and an understory of tamarisk averaging 5 m in height. The site contains two channels of the Bill Williams River, one along the southwestern edge of the site and the other through the center of the site. Areas of bulrush and cattail are present in both channels, and patches of young Goodding willow and cottonwood are growing in sandy areas along the channel that runs along the southwestern edge of the site. Overall canopy closure is <50%. Both channels of the Bill Williams River contained surface water through July, but soils away from the channels were dry and sandy. Sparse canopy closure and lack of surface water or damp soils underneath the vegetation make this site unlikely to support resident flycatchers. No resident willow flycatchers have been detected at this site since 2003, and we recommend biennial surveys unless floods occur that have the potential to alter the hydrology or vegetation of the area.

No willow flycatchers were detected. We surveyed the site five times, totaling 8.0 observer-hours. Cowbirds were detected on all but one visit, and no evidence of livestock use was observed.

Beaver Pond

Area: 21.7 ha Elevation: 165 m

This mixed-native site consists of cottonwood and Goodding willow averaging 15 m in height with an understory of tamarisk along the Bill Williams River. Areas not immediately adjacent to the river channel are vegetated by tamarisk and honey mesquite 5–7 m in height. Cattail and bulrush are present along most of the river channel. Overall canopy closure at the site is <50%. A channel of the Bill Williams River was flowing along the edge of the site throughout the flycatcher breeding season, and an

old channel in the center of the site contained small pools of water. Soils under the vegetation, however, were completely dry. Sparse canopy closure and lack of surface water or damp soils underneath the vegetation make this site unlikely to support resident flycatchers. No resident willow flycatchers have been detected at this site since 2003, and we recommend biennial surveys unless floods occur that have the potential to alter the hydrology or vegetation of the area.

No willow flycatchers were detected. We surveyed the site five times, totaling 5.0 observer-hours. Cowbirds were detected on all visits. No signs of livestock were observed.

Bill Williams Site #8

Area: 10.3 ha Elevation: 168 m

This narrow, linear site encompasses the river channel approximately 3 km upstream from the Mineral Wash Complex, at the confluence of Mohave Wash and the Bill Williams River. This section of the river is confined between high cliffs on both banks. Cottonwood and willow trees 18 m in height line a flowing river channel, with clumps of tamarisk also present in the understory throughout the site. Overall canopy closure is 25–50%. This site had flowing water in the river channel throughout the flycatcher breeding season, but soils beneath the vegetation were very dry. Sparse canopy closure and lack of surface water or damp soils underneath the vegetation make this site unlikely to support resident flycatchers. No resident willow flycatchers have been detected at this site since 2003, and we recommend biennial surveys unless floods occur that have the potential to alter the hydrology or vegetation of the area.

No willow flycatchers were detected. We surveyed the site five times, totaling 4.5 observer-hours. Cowbirds were detected on all but one visit and no evidence of livestock use was observed.

Ground Reconnaissance Results

Field personnel spent a total of 27.4 person-hours conducting habitat reconnaissance and/or habitat evaluation and opportunistic broadcast surveys along the Bill Williams River corridor. We revisited seven areas that had been identified in 2006 or 2007 and visited four new areas (Cliff Pond, Downstream of Site #8, New River, and East of Planet Ranch; see Figures 2.3 and 2.4). The following descriptions are organized from downstream to upstream along the Bill Williams River.

"BURN EDGE"

Burn Edge consists of two areas of riparian vegetation northeast of where an arm of Lake Havasu follows a channel of the Bill Williams River. The eastern patch is located approximately 100 m north of Site #2 and consists of tamarisk 8–10 m in height, with 14 m Goodding willow scattered throughout the site. Ground cover in portions of the site consists of thick, dead, fallen woody vegetation. Canopy closure averages 80%. Although no standing water or saturated soils were present under the vegetation, a small arm of Lake Havasu follows a channel of the Bill Williams River through the site.

The western patch of Burn Edge is located approximately 300 m northeast of Site #11. The northwestern end of the site is on the edge of an area that burned in 2006, and scattered 3-m-tall Goodding willow and tamarisk have sprouted in this area. The burned area ends at a small, grassy opening with a pond on the western end. To the southeast of the pond, the overstory comprises Goodding willow and cottonwood 12–15 m in height, and tamarisk 3–5 m in height forms the understory. An understory of 3–5 m tamarisk is present throughout the site, and ground cover in portions of the site consists of thick, dead, fallen woody vegetation. Canopy closure is highly variable, and ranges from 20% to 90%, depending on the

density of the tamarisk. The pond held standing water during site visits in late May and mid-June. Although soils under the vegetation were dry, there was evidence that water had been present under the vegetation at one time. This site should be visited in future years to assess any changes in hydrology that might increase the suitability of the area for flycatchers.

No willow flycatchers were detected at Burn Edge. We surveyed the eastern patch once and the western patch twice, totaling 5.0 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

"LAST GASP"

Last Gasp is depicted as a wetland on the U.S. Geological Survey (USGS) Monkey's Head 7.5-min topographic map. The area consists of an overstory of cottonwood and Goodding willow up to 15 m in height and a tamarisk understory 5 m in height. Canopy closure is highly variable. Stagnant surface water was present in small pools along a muddy channel during site visits in May and June. Soils under the vegetation and away from the muddy channels were dry. This site should be visited in future years to assess any changes in hydrology that might increase the suitability of the area for flycatchers.

No willow flycatchers were detected at Last Gasp. We surveyed the site twice, totaling 2.3 observer-hours. Cowbirds were detected on both visits, and no evidence of livestock use was observed.

"RIVER END"

This site is approximately 350 m southeast of Last Gasp. The southeastern corner of the site is adjacent to standing water within the Bill Williams River, at the point where the river goes subsurface. The vegetation at River End consists of a mosaic of dense tamarisk 5 m in height, a sparse overstory of emergent willow and cottonwood, and clumps of mesquite trees, many of which are dead. Canopy closure ranges from 25 to 70%. Small islands of cattail marsh are confined to the river channel, and during site visits saturated soils were present only along the river channel. Because soils within the site were very dry, we do not recommend revisiting this site unless floods occur that have the potential to alter the hydrology of the area.

No willow flycatchers were detected. We surveyed the site twice, totaling 2.0 observer-hours. Cowbirds were detected on both visits, and no evidence of livestock use was observed.

"FLOODED REFUGE ROAD"

Flooded Refuge Road is located approximately 300 m southeast of Site #5 along the old refuge road, which was washed out during a 2004–2005 winter flood. Vegetation at the site consists of scattered, emergent willows and cottonwoods and an understory of tamarisk. Vegetation throughout the site is patchy, with dry, sandy openings and dry river channels bisecting the area. Overall canopy closure is around 50%. No standing water or saturated soils were present during site visits in mid-May and late June. We do not recommend surveying this site in future years unless floods occur that have the potential to alter the hydrology of the site.

No willow flycatchers were detected. We surveyed the site twice, totaling 4.5 observer-hours. Cowbirds were detected on both visits, and no evidence of livestock use was observed.

Figure 2.4. Bill Williams River NWR habitat evaluation 2008, continued.

"NEW WILLOW"

This area is approximately 1.4 km southeast of Site #5. Goodding willow and cottonwood to heights of 10 m compose a patchy overstory in this area. Understory vegetation is primarily tamarisk of varying height, and canopy closure is around 70%. Cattail and honey mesquite are also present, and areas of young cottonwood and Goodding willow occur to the east of the site. Soils under the vegetation were dry to damp during site visits in late May and late June, with the nearest surface water approximately 200 m away. The areas of young vegetation should be reevaluated in future years.

No willow flycatchers were detected. We surveyed the site twice, totaling 2.5 observer-hours. Cowbirds were detected on both visits, and no evidence of livestock use was observed.

"CLIFF POND"

Cliff Pond is located approximately 350 m south of New Willow and consists of a stand of Goodding willow and cottonwood 10–15 m in height with a dense, tamarisk understory. The site is bordered to the west by rocky cliffs and desert upland, and to the east by a dry wash. Standing water that was observed during helicopter reconnaissance in mid-April was not confirmed because dense vegetation prohibited access of the entire area. During the site visit, small areas of saturated soils were present in cattail stands along the wash. This area should be reevaluated in future years to determine the vegetation and hydrological characteristics of the interior of the site.

No willow flycatchers were detected. We surveyed the site once, totaling 0.8 observer-hours. Cowbirds were detected, and no evidence of livestock use was observed.

"DOWNSTREAM FROM SITE #8"

We started our habitat evaluation approximately 1 km west of Site #8 and evaluated approximately 600 m of vegetation along the Bill Williams River toward Site #8. The site consists primarily of Goodding willow and cottonwood 8–10 m in height with a tamarisk understory. Canopy closure is highly variable and ranges from 40 to 70%. Cattail and bulrush are present along the river, as are young willows. During the site visit, soils were dry under the vegetation away from the river. We do not recommend surveying this site in future years unless floods occur that have the potential to alter the hydrology of the site.

No willow flycatchers were detected. We surveyed the site once, totaling 0.3 observer-hours. Cowbirds were detected, and no evidence of livestock use was observed.

"UPSTREAM FROM SITE #8"

We evaluated two relatively small areas upstream of Site #8. The first is approximately 300 m east of Site #8 and is bordered by an open pond to the northwest and a marsh to the north. Vegetation in this area consists of an overstory of cottonwood up to 17 m in height and an understory of tamarisk. Arrowweed also occurs in the understory in areas with little canopy cover. Canopy cover is patchy and ranges from 50 to 70%. Surface water and saturated soils were limited to the marshy areas on the edge of the site, and soils in the remainder of the site were damp during the site visit in mid-May. Canopy closure in this area is generally too low to provide suitable flycatcher habitat.

The second area we evaluated is approximately 200 m north of the first and is bordered to the north by desert uplands. The overstory consists of scattered Goodding willow and cottonwood, while the understory consists of tamarisk up to 2 m in height and dead cattails. Canopy closure is <50%. Approximately 40% of the site was inundated during the site visit in early June, with another 30% having

saturated or damp soils. This area could become suitable flycatcher habitat if the tamarisk matures, and it should be evaluated in future years.

No willow flycatchers were detected. We surveyed the site twice, totaling 2.5 observer-hours. Cowbirds were detected on both visits, and no evidence of livestock use was observed.

"PLANET RANCH"

We started our habitat evaluation approximately 200 m east of the southern portion of Upstream from Site #8, and evaluated an area extending 400 m east of the starting point. Goodding willow and cottonwood up to 20 m in height make up a scattered overstory, while tamarisk up to 7 m in height form a relatively continuous understory. The southern edge of the site is more sparsely vegetated than the center and has many fallen cottonwoods. The center of the site has small channels lined with dead sedges and cattails. No standing water or saturated soils were present in mid-May, though soils were damp in approximately 75% of the site. The central portion of the site has the structure typical of flycatcher habitat, and this area should be evaluated in future years to determine hydrologic conditions.

No willow flycatchers were detected. We surveyed the site once, totaling 2.3 observer-hours. Cowbirds were detected, and no evidence of livestock use was observed.

"NEW RIVER"

New River is located approximately 300 m south of Planet Ranch and consists of a stringer of young Goodding willow and cottonwood 3–6 m in height along the Bill Williams River. The stringer varies from 10 to 30 m wide. We evaluated a section 500 m long, and the habitat continues upstream beyond the area we evaluated. The stringer is surrounded by open, sandy areas. Cattail and bulrush are present along the river, which contained flowing water during the visit in mid-May. This area is currently too young and narrow to provide suitable flycatcher habitat but should be monitored in future years.

"EAST OF PLANET RANCH"

This area is approximately 1 km upstream from Planet Ranch. We evaluated this area because large trees are visible on the aerial photograph. The large trees are a scattered stringer of cottonwood approximately 25 m in height. The understory consists of dense tamarisk up to 10 m in height. The area was extremely dry during the site visit and does not resemble suitable flycatcher habitat.

Ahakhav Tribal Preserve, Arizona

The Ahakhav Tribal Preserve encompasses backwater areas along the Colorado River near Parker, Arizona, and includes restoration sites. We initially surveyed Deer Island and then added Willow Beach as a survey area midway through the season. We also visited the CRIT 9 restoration area.

Willow Beach

Area: 2.0 ha Elevation: 104 m

This site consists of an area of planted cottonwood bordering a backwater channel. The interior of the site consists of an understory of arrowweed and an overstory of cottonwoods up to 10 m in height. Many of the cottonwoods have sparse leaves, and overall canopy closure is <25%. The backwater channel is lined with seep willow (*Baccharis* sp.), and the edges of the restoration site have areas of tamarisk and mesquite. Surface water was present in the backwater channel and in a small pond during site visits in

June and July. This site does not resemble suitable flycatcher habitat and further surveys are not recommended.

No willow flycatchers were detected. We surveyed the site three times, totaling 1.5 observer-hours. Cowbirds were detected on two surveys, and no evidence of livestock use was present.

Deer Island

Area: 91.6 ha Elevation: 104 m

This site consists of a narrow strip of mixed-native vegetation on the edge of a long backwater slough with extensive areas of cattails. The only dense, woody vegetation occurs in a strip approximately 5 m wide on the edge of the slough and consists of tamarisk and screwbean mesquite up to 6 m in height and an understory of arrowweed. More than 5 m from the water, vegetation is primarily arrowweed with widely scattered tamarisk and mesquite. Canopy closure is <50%. The southern side of the slough has a steep, high bank, and woody vegetation is perched several meters above the water level. The north bank is not as high, with woody vegetation approximately 1 m above the water level. Although extensive areas of inundated and saturated soils existed in the slough and the adjacent cattails, water did not extend into the woody vegetation at any time during the survey season.

One unpaired, resident flycatcher was detected. One additional willow flycatcher was detected for which residency was not confirmed. Details of color-banding and occupancy are presented in Chapter 3. Five surveys were completed at the site, totaling 14.5 observer-hours. Cowbirds were detected on all visits. No evidence of livestock use was observed.

Ground Reconnaissance Results

"RESTORATION"

This site consists of planted stands of cottonwood and Goodding willow up to 15 m in height. The site also contains patches of honey mesquite 4–7 m tall. The edges of the site have coyote willow up to 3 m in height. Understory is minimal and consists of young willows and cottonwoods. Overall canopy closure is <50%. Soils within the site were dry and sandy during the site visit in mid-June. This restoration area does not currently provide suitable habitat for flycatchers, and we do not recommend further surveys unless additional management actions create a denser understory and greater canopy closure.

No willow flycatchers were detected. We surveyed the site once for a total of 0.8 observer-hours.

Big Hole Slough, California

Big Hole Slough

Area: 16.6 ha Elevation: 82 m

This mixed-native site consists of a cattail marsh edged with narrow bands of coyote willow 5 m in height. Away from the marsh, the site contains tamarisk and honey and screwbean mesquite 8 m in height with an understory of arrowweed. A few tall Goodding willow and cottonwood are present at the site. Overall canopy closure is approximately 50%. The marsh contained standing water throughout the survey season.

We detected one willow flycatcher on 9 June. The site was surveyed five times, totaling 9.8 observer-hours. Cowbirds were detected on all visits, often in large flocks. No livestock use was observed.

Ehrenberg, Arizona

Ehrenberg

Area: 4.7 ha Elevation: 78 m

This mixed-native site consists primarily of a canopy of cottonwood and Goodding willow 15 m in height with an understory of arrowweed. Approximately 5% of the site contains a cattail marsh surrounded by stands of coyote willow. Most of the coyote willows were leafless and dead by the end of the survey season. The periphery of the site is vegetated with a mix of tamarisk and mesquite. Canopy closure at the site is approximately 50%. The cattail marsh contained saturated soils in May and July, and the site is separated from the Colorado River by a levee. The coyote willows were the only dense understory taller than 3 m, and the death of the willow stands makes this site less suitable for flycatchers.

No willow flycatchers were detected. The site was surveyed five times, totaling 7.3 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

Cibola National Wildlife Refuge, Arizona and California

CVCA

Area: 26.2 ha Elevation: 73 m

This restoration area consists of a mosaic of rectangular cells of cottonwood, Goodding willow, and coyote willow of varying size and density. Each cell generally contains a single species and age class. The tallest cottonwoods and willows are around 8 m in height, and canopy closure in the densest areas is 80–90%. The site is flood irrigated and contained varying amounts of surface water through the season.

Two willow flycatchers were detected on 18 June. The site was surveyed five times, totaling 8.3 observer-hours. Large flocks of cowbirds were detected on all visits, and no evidence of livestock use was observed.

Cibola Nature Trail

Area: 13.7 ha Elevation: 70 m

This restoration site consists of a mosaic of cottonwood, Goodding willow, and mesquite. Approximately half the site consists of scattered screwbean and honey mesquite up to 5 m in height with a thick understory of seep willow. The northern half of the site contains an extensive stand of Goodding willow 8 m in height. The northern edge of the willow stand has canopy closure <25% and many of the willow are dead. The southern half of the willow stand has canopy closure around 70%. The southwestern corner of the site has a small stand of cottonwoods, and stringers of cottonwoods up to 18 m in height occur throughout the site. The site is flood irrigated and contained varying amounts of surface water through the season.

We detected one willow flycatcher on 6 June. The site was surveyed five times, totaling 4.0 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

Cibola Island

Area: 4.2 ha Elevation: 70 m

This mixed-native site is approximately 9.5 km southwest of Cibola Nature Trail. The site runs north to south, extending approximately 500 m lengthwise, with a width of 100 m. Dirt roads border the site to the north, east, and west. Open farm fields lie across the eastern road, with irrigation channels alongside the road. An irrigation canal empties into the northern end of the site, creating an open, marshy area down the center of the site. Between this marshy area and the western road, vegetation consists of an overstory of Goodding willow 10–12 m in height with an understory of tamarisk 5–7 m in height. Canopy closure within the willows is 80%. A narrow strip had been bulldozed along the western road and planted with Goodding willow and cottonwood poles that had barely sprouted in mid-June. The eastern edge of the marsh is lined with a narrow strip of tamarisk 5–6 m in height with a few emergent Goodding willows on the marsh edge. Between the tamarisk strip and the eastern road, vegetation consists of honey mesquite and bushy arrowweed. The marsh was dry in May but contained up to 50 cm of water in June and July.

We detected one willow flycatcher on 15 May, two on 6 June, and two on 18 June. The site was surveyed five times, totaling 5.7 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

Three Fingers Lake

Area: 67.9 ha Elevation: 65 m

This mixed-exotic site consists of the area immediately surrounding a dredged backwater channel of the Colorado River. The edges of the channel are vegetated by cattail and bulrush. The dominant woody vegetation is tamarisk, which is densest immediately adjacent to the channel and reaches heights of 6 m. A few large Goodding willow are also present. Away from the channel, the tamarisk is shorter and sparser and is mixed with honey and screwbean mesquite with an understory of arrowweed. Canopy closure along the shore is approximately 50%. Water was present in the backwater channel throughout the season, but there was no water under the woody vegetation.

We detected one willow flycatcher on 18 May, two on 7 June, and four on 19 June. The site was surveyed five times, totaling 13.0 observer-hours. Large numbers of cowbirds were detected on all visits, and no evidence of livestock use was observed.

Cibola Lake North and West

Cibola Lake North: Area: 8.5 ha Elevation: 64 m
Cibola Lake West: Area: 6.8 ha Elevation: 64 m

These mixed-exotic sites border Cibola Lake. The perimeter of each site adjacent to the lake is vegetated by cattail and bulrush. Areas immediately inland from the cattail marshes are vegetated by dense tamarisk 4–6 m in height with scattered Goodding willow. The interiors of the sites have patchy vegetation with a mix of tamarisk, arrowweed, and open sandy areas. Canopy closure along the marsh edges is 50–70%, while the interiors of the sites have canopy closure <25%. Except for along the shores, soils within the interior of the sites were dry throughout the survey period.

We detected one willow flycatcher on 8 June and one on 18 June at Cibola Lake North. At Cibola Lake West we detected one flycatcher on 20 May, two on 9 June, and two on 18 June. Each site was surveyed

five times, totaling 11.0 observer-hours for Cibola Lake North and 11.5 observer-hours for Cibola Lake West. Cowbirds were detected on all visits to both sites, and no evidence of livestock use was observed.

Walker Lake

Area: 11.4 ha Elevation: 64 m

This mixed-exotic site is located along the northeastern edge of Walker Lake. The majority of the site consists of very dense tamarisk approximately 5 m in height. The southeastern end of the site contains scattered emergent Goodding willow up to 20 m in height, as well as a couple of emergent cottonwoods. This portion of the site also contains a small opening with dead cattails and a small patch of half-dead coyote willow. Walker Lake contained standing water and saturated soil throughout the survey season. Areas of the site adjacent to Walker Lake had standing water and saturated soils in May, though these soils were only damp in June and July. Soils in the interior of the site were dry throughout the survey season.

We detected two willow flycatchers on 7 June. The site was visited five times, totaling 13.0 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

Imperial National Wildlife Refuge, Arizona and California

Draper Lake

Area: 4.6 ha Elevation: 63 m

This site is on the northern edge of Draper Lake, which lies approximately 200 m west of the Colorado River and is surrounded by extensive areas of cattail marsh. This site burned prior to the 2003 survey season and was first surveyed again in 2006. Vegetation immediately adjacent to the cattail marsh consists of a narrow (5–10 m) strip of young, dense tamarisk up to 7 m in height with over 90% canopy closure. The central portion of the site consists of a stand of coyote willow approximately 100 m x 50 m. Many of these willows are dead, and canopy cover is around 70%. The northern end of the site consists of scattered tamarisk clumps up to 5 m in height, an understory of arrowweed, and many open areas. Canopy closure in this portion of the site is <25%. Standing water was present in Draper Lake during the site visit in May. Surveys at this site were discontinued because the stands of coyote willow are dying, and the site does not provide habitat suitable for resident flycatchers.

One willow flycatcher was detected on 27 May. The site was surveyed once, totaling 1.5 observer-hours. Cowbirds were detected, and there was no evidence of livestock use.

Paradise

Area: 7.8 ha Elevation: 62 m

This site is mixed-native habitat, with stringers of cottonwood and Goodding willow, 15–20 m in height, bordering a small cattail marsh. Tamarisk (5 m in height) and arrowweed (3 m in height) make up the understory. The cottonwoods and willows are separated from the Colorado River by a narrow (50-m-wide) strip of dense tamarisk. A cattail marsh borders the site to the south. Overall canopy closure is approximately 25%. Standing water was present within the marsh throughout the survey season.

We detected two willow flycatchers on 27 May. The site was surveyed five times, totaling 10.9 observer-hours. Cowbirds were detected on every visit, and no evidence of livestock use was observed.

Hoge Ranch

Area: 20.7 ha Elevation: 61 m

This mixed-exotic site is dominated by tamarisk 4–6 m in height, with a few emergent cottonwoods and Goodding willows (15 to 18 m in height) at the southern end of the site near the old ranch. Linear marshes with cattail, bulrush, and common reed (*Phragmites* sp.) occupy less than 20% of the interior of the site, and there are a few patches of coyote willow. Canopy closure is approximately 50%. The marshes in the interior of the site contained fluctuating amounts of standing water and saturated soil throughout the survey season, but the interior of the site was not explored sufficiently to determine the percentage of the site that was inundated. The site also borders the Colorado River.

We detected two willow flycatchers on 31 May, four on 13 June, and one on 22 June. The site was surveyed five times, totaling 9.8 observer-hours. Cowbirds were detected on all surveys, and there was evidence of burros using the site.

Adobe Lake

Area: 7.6 ha Elevation: 60 m

This mixed-exotic site consists primarily of dense tamarisk (5 to 7 m in height) with many dead branches in the understory. There are scattered Goodding willows up to 10 m in height. Canopy closure within the site is 70–90%. The site is adjacent to the Colorado River, but hydrological conditions in the interior of the site were undetermined.

We detected 10 willow flycatchers on 31 May and 2 on 15 June. One of the flycatchers detected on 31 May was banded on at least one leg. The site was surveyed five times, totaling 5.5 observer-hours. Cowbirds were detected on three visits, and no evidence of livestock use was observed.

Rattlesnake

Area: 7.6 ha Elevation: 60 m

This mixed-native site is a patchwork of emergent Goodding willow, strips of dense coyote willow 6–8 m in height, and tamarisk. Tamarisk is widespread in patches throughout the site but is not the dominant vegetation. Canopy closure is 70–90%. Large cattail marshes separate this site from the Colorado River. Portions of the site held standing water throughout the season.

We detected three willow flycatchers on 30 May and one on 13 June. The site was surveyed five times, totaling 8.9 observer-hours. Cowbirds were detected on all surveys, and there was no evidence of livestock use.

Clear Lake/The Alley

Area: 8.3 ha Elevation: 59 m

Vegetation at this site is primarily exotic, consisting of monotypic tamarisk 8–10 m in height. Emergent Goodding willows, up to 13 m in height, are scattered throughout the site. The tamarisk is mature, with large amounts of deadfall ground cover, and canopy closure is approximately 90%. The site is surrounded on the east, north, and west by upland desert and is bordered on the south by cattail marshes and common reed. A narrow, backwater channel runs northward from the Colorado River into the center

of the site, and soils immediately adjacent to the channel were inundated or saturated. Soils in the interior of the site, however, were dry throughout the survey season.

We detected six willow flycatchers on 1 June. We surveyed the site five times for a total of 11.6 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Nursery NW

Area: 7.0 ha Elevation: 58 m

This mixed-exotic site lies between the Colorado River and a cattail marsh. The dominant vegetation is tamarisk approximately 5 m in height with an understory of common reed. Mesquite trees are scattered along the western edge of the site. The eastern edge of the site, adjacent to the cattail marsh, has a stand of Goodding willow 9 m in height. Overall canopy closure is around 70%. Surface water was present under the willows in May.

No willow flycatchers were detected. The site was surveyed five times, totaling 3.1 observer-hours. Cowbirds were detected on all visits, and there was no evidence of livestock use.

Imperial Nursery

Area: 1.4 ha Elevation: 58 m

This site is a cottonwood planting managed by the Imperial NWR. The cottonwoods are approximately 12 m in height. The edges of the site are vegetated by arrowweed and seep willow, with a few honey mesquite in the northwestern corner of the site. The understory is very sparse, and canopy closure is approximately 90%. The site is bordered to the north by a patchwork of cattails, common reed, and tamarisk. This site is flood irrigated.

No willow flycatchers were detected. The site was surveyed five times, totaling 2.2 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Ferguson Lake

Area: 21.1 ha Elevation: 57 m

The Ferguson Lake site is on a strip of land between Ferguson Lake and the Colorado River. Vegetation is mixed-native, with scattered, emergent Goodding willow 10 m in height along the western edge of the site bordering Ferguson Lake. Tamarisk 5–6 m in height is the dominant understory species, and it forms a continuous canopy in portions of the site. The site also contains patches of arrowweed with scattered screwbean mesquite and little canopy cover. The northwestern corner of the site up to 50 m from the lakeshore had damp soils in May and June and standing water in July. A cattail marsh is present in the southwestern corner of this site; it had standing water when it was visited in late May.

We detected 12 willow flycatchers on 29 May. The site was surveyed five times, totaling 6.8 observer-hours. Cowbirds were detected on all but one visit, and no signs of livestock use were observed.

Ferguson Wash

Area: 6.8 ha Elevation: 58 m

This mixed-exotic site, at the outflow of Ferguson Wash into Ferguson Lake, is dominated by dense, mature tamarisk approximately 7 m in height, with dense deadfall in the understory. A few scattered, emergent Goodding willows are present near the lake, and canopy closure is around 70%. The site is bordered on the lakeside by cattails and bulrush and on the upland side by desertscrub. A backwater channel penetrates to the interior of the site, although the banks along the channel are abrupt and do not allow water to flow under the vegetation in this area. Another backwater channel runs along the southeastern edge of the site. The banks along this channel are less abrupt, allowing water to penetrate a few meters into the woody vegetation in a few places along the channel edge. Soils in the interior of the site were dry throughout the survey season. Because the site contains so little water under mature vegetation, and soils in the majority of the site are completely dry, we recommend biennial surveys at this site.

We detected two willow flycatchers on 29 May. The site was surveyed five times, totaling 9.2 observer-hours. Cowbirds were recorded on all visits, and evidence of burros was present in the site.

Great Blue Heron

Area: 7.1 ha Elevation: 58 m

This site, on the eastern shore of Martinez Lake, consists of mixed-exotic vegetation. Near the shore of Martinez Lake, Goodding willows form an overstory 15 m in height, with an understory of tamarisk, common reed, and giant reed (*Arundo* sp.). Canopy closure in this area is 80%. The center of the site has several fallen willows. Farther from the lake, the site is vegetated by scattered arrowweed and tamarisk 6 m in height, with canopy closure <50%. Standing water was present in May, and saturated soils were noted within the site throughout the survey season near Martinez Lake.

We detected two willow flycatchers on 23 May and one on 14 June. The site was surveyed five times, totaling 13.8 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

Mittry Lake, Arizona and California

Mittry West

Area: 4.4 ha Elevation: 48 m

The center of this mixed-native site is dominated by Goodding willow 12 m in height with a dense understory of arrowweed and tamarisk. Canopy closure is approximately 80%. Honey and screwbean mesquite are scattered throughout the site but are more common near the periphery. There are patches of cattail within the site. Surface water was present in the site during May and June, with saturated soils present until July.

We detected two willow flycatchers on 28 May. The site was visited five times, totaling 10.5 observer-hours. Cowbirds were detected during all surveys, and no evidence of livestock use was observed.

Mittry South

Area: 15.2 ha Elevation: 46 m

This monotypic tamarisk site lies immediately adjacent to Mittry Lake. Vegetation at the site is very dense, with abundant dead branches and deadfall in the understory. Canopy closure within the tamarisk is >90%, and canopy height is approximately 8 m. The site is bordered to the south by Mittry Lake, and the edge of the lake is vegetated by cattail, bulrush, and common reed. Water from the lake does not extend under the woody vegetation, and soils in the site were very dry throughout the survey season.

We detected two willow flycatchers on 28 May. The site was visited five times, totaling 6.5 observer-hours. Cowbirds were detected during all surveys, and no evidence of livestock use was observed.

Yuma, Arizona

Gila Confluence North

Area: 2.2 ha Elevation: 40 m

This mixed-native site borders the northern side of the Colorado River at the confluence of the Gila and Colorado Rivers. Overstory vegetation at the site is a combination of Goodding willow and cottonwood 9 m in height. Dense stands of these trees surround a cattail marsh near the center of the site. Cattail marsh is also present along the river, and there is an open area of common reed in the center of the site. Canopy closure is variable and averages around 50%. Arrowweed, tamarisk, and seep willow are common in the understory. Surface water was present in the marshy areas along the edge of the river throughout the survey season, and shallow pools of water were also present in the common reed patch in July.

We detected five willow flycatchers on 2 June, five on 16 June, and two on 21 June. The site was surveyed five times, totaling 10.25 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

DISCUSSION

The areas occupied in 2008 by breeding flycatchers (Pahranagat NWR, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams River NWR) consistently held resident and breeding flycatchers in previous years (McKernan and Braden 2002, McLeod et al. 2008a; details of residency and breeding in 2008 are presented in Chapters 3 and 4 of this document). We detected unpaired, resident flycatchers in two new areas. One resident flycatcher was detected at Iceberg Canyon on the Lake Mead Delta. This site consists of newly developed vegetation and had not been previously surveyed. The development and persistence of vegetation at this site will likely be influenced by the level of Lake Mead. A resident flycatcher was also detected on the Ahakhav Tribal Preserve at Deer Island, which we had not surveyed prior to 2008. This was the first detection of a resident willow flycatcher south of Bill Williams since 2003, although we did not survey any areas between Bill Williams and Big Hole Slough in 2003–2007. Deer Island does not resemble typical occupied flycatcher habitat. Dense vegetation occurs only in a narrow strip on the edge of a long backwater slough, overall canopy closure is very sparse, and canopy height is low. Future surveys will reveal whether this area is typically occupied by flycatchers or if flycatcher occupancy at Deer Island was an anomalous occurrence.

The association between surface water and flycatcher occupancy and breeding is noted consistently in the literature, and we observed an association between the presence of breeding flycatchers and surface water at Bill Williams, with flycatchers breeding only in years when sites contained standing water (McLeod et al. 2008b, this document). Factors in addition to the presence of standing water during the breeding season appear to be influencing the presence and numbers of flycatchers at Topock Marsh. The amount of standing water throughout the entire Topock study area was markedly reduced in 2005 compared to 2003–2004 and 2006–2008, and sites in 2008 were as wet or wetter than in any previous year. The number of flycatchers recorded at Topock since 2003 does not appear to be related to the amount of standing water present during the breeding season, with 25, 67, 41, 37, 31, and 30 adults recorded in 2003–2008, respectively. Factors such as reproductive rates, survival, or other abiotic conditions may be influencing the demographics of this local population. Hydrologic conditions within the sites at Topock prior to mid-May of each year are unknown; conditions prior to flycatcher arrival could influence habitat conditions and flycatcher occupancy.

In an effort to locate all potentially suitable willow flycatcher habitat within the Bill Williams River NWR, we continued habitat reconnaissance and opportunistic surveys initiated in 2006 and 2007. We revisited most sites that had been identified in 2006 or 2007 as warranting further investigation and evaluated four additional areas. Although the Bill Williams River NWR contains the largest expanse of native cottonwood-willow forest on the lower Colorado River, at this time vegetation structure and hydrological conditions along most of the river corridor are not characteristic of willow flycatcher breeding habitat. We determined that several of the areas we revisited are unlikely to support flycatchers unless the Bill Williams River experiences floods that might alter hydrological conditions.

We continued to observe habitat changes in lower Grand Canyon and on the Lake Mead Delta as water levels in Lake Mead continued to decline between 2007 and 2008. Several sites that were occupied in 2006 but were dead or dying by the end of the 2007 survey season were not surveyed in 2008 because of the lack of live vegetation. Only one new site, at the mouth of Iceberg Canyon, had emerged between 2007 and 2008; this site had the only flycatcher detected in Grand Canyon in 2008. If Lake Mead continues to decline, we expect this pattern to continue, with once-suitable habitat becoming elevated above the water table and vegetation emerging on newly exposed sediments.

Although many flycatchers were recorded at sites surveyed south of the Colorado River Indian Reservation until 15 June, and 23 detections were recorded post 15 June, monitoring results at these sites suggest these flycatchers were not resident or breeding individuals. Based upon the variation in total numbers of flycatchers detected at a particular site over the survey period (e.g., 10 flycatcher detections at Adobe Lake on 31 May, 2 on 15 June, and 0 on three subsequent surveys), and the overall lack of territorial, aggressive behaviors exhibited toward conspecific broadcasts, willow flycatchers detected these sites were most likely migrants. These results are consistent with those recorded in 2003–2007 (McLeod et al. 2008a). One banded flycatcher was detected at Adobe Lake on 31 May, but the observer was unable to determine the color combination. We banded migrant willow flycatchers at sites on the extreme southern stretches of the Colorado River near Yuma in 2003–2007, and without confirmation of the color combination, we cannot determine whether the flycatcher was banded as a resident Southwestern Willow Flycatcher or whether it was banded during migration and might belong to a different subspecies.

In 2008 we implemented a biennial survey schedule at selected sites in study areas where resident flycatchers have not been documented in the last 10 years of surveys. Sites were selected for biennial surveys based on the absence of damp or wet soils within the site and/or the relative absence of dense vegetation that might provide suitable nesting habitat for flycatchers. Ground reconnaissance completed during the 2008 field season revealed that Havasu NE and Ferguson Wash do not contain wet soils within the vegetation, and we recommend that these sites be added to the biennial schedule. In addition, we

identified several sites at Bill Williams where no resident flycatchers have been detected since 2003 and where surface water exists only in river channels and not within the vegetation. We recommend that these sites (Site #2, Site #11, Beaver Pond, Mineral Wash, and Site #8) be surveyed on a biennial basis as well.

Chapter 3

COLOR-BANDING AND RESIGHTING

INTRODUCTION

Long-term monitoring of willow flycatchers of known identity, sex, and age is the only effective way to determine demographic life history parameters such as annual survivorship of adults and young, site fidelity, seasonal and between-year movements, and population structure. Thus, as an integral part of our studies, we captured and uniquely color-banded as many willow flycatchers as possible, allowing field personnel to resight individuals throughout the breeding season, as well as in subsequent years. Resighting consisted of using binoculars to determine the identity of a color-banded flycatcher by observing, from a distance, the unique color combination on its legs. This allowed field personnel to detect and monitor individuals without recapturing each bird. This was our sixth consecutive year of color-banding studies and builds upon color-banding initiated at these sites in 1997 (McKernan and Braden 1998).

METHODS

Color-banding

From early May through mid-August, we captured, uniquely color-banded, and subsequently monitored adult and nestling willow flycatchers at all study areas where resident willow flycatchers were detected. The color-banding effort also included opportunistic banding at Key Pittman Wildlife Management Area in Nevada (in cooperation with Nevada Division of Wildlife), along Las Vegas Wash (in cooperation with Southern Nevada Water Authority), and in St. George, Utah (in cooperation with Utah Division of Wildlife Resources).

Adult flycatchers were captured with mist-nets, which provide the most effective technique for live-capture of adult songbirds (Ralph et al. 1993). We used a targeted capture technique (per Sogge et al. 2001), whereby a variety of conspecific vocalizations were broadcast from a CD player and remote speakers to lure territorial flycatchers into the nets. In addition, we used "passive netting," whereby several mist-nets were erected and periodically checked, with no broadcast of conspecific vocalizations. We banded each adult willow flycatcher with a single, numbered U.S. federal aluminum band on one leg and a colored metal band on the other. We coordinated all color combinations with the Federal Bird Banding Laboratory and all other Southwestern Willow Flycatcher banding projects to minimize replication of color combinations. For each color-banded bird recaptured, we visually inspected the legs and noted any evidence of irritation or injury that may be related to the presence of leg bands.

Nestlings were banded at 8 to 10 days of age, when they were large enough to retain the leg bands, yet young enough that they would not prematurely fledge from the nest (Whitfield 1990, Paxton et al. 1997). Nestlings were banded only when the location of the nest was such that nest access and removal/replacement of the nestlings would not endanger the nest, nest plant, or nestlings. Nestlings were also banded with a single, numbered federal band on one leg and a metal color-band on the other leg. In previous years, we banded each nestling only with a single federal band, identifying it as a returning nestling in the event it returned in a subsequent year.

For each captured adult willow flycatcher, we recorded morphological measurements including culmen, tail, wing, fat level, and molt onto standardized data forms (Appendix A). Sex was determined based on the presence of a cloacal protuberance in males or brood patch and/or egg(s) in the oviduct for females. Captured flycatchers lacking breeding characteristics and not observed engaging in male advertising song (see below) were sexed as unknown. Flycatchers with retained primary, secondary, and/or primary covert feathers (multiple aged remiges) were aged as second year adults, and those without (uniformly aged remiges) were aged as after second year (per Kenwood and Paxton 2001 and Koronkiewicz et al. 2002). Individuals in juvenile plumage (unworn flight feathers and body plumage with broad, buff colored wing bars and fleshy gape) were aged as hatch year.

Resighting

We determined the identity of a color-banded flycatcher by observing with binoculars, from a distance, the unique color combination on its legs. Typically, territories and active nests were focal areas for resighting, but entire sites were surveyed. Field personnel typically spent the early part of each morning color-banding, and directed their efforts to resighting as daylight increased and flycatchers became more difficult to capture. All banding, monitoring, and survey field personnel coordinated resighting efforts and recorded observations of color-banded and unbanded flycatchers onto standardized data forms (Appendix A). For resighted flycatchers (i.e., one for which at least one leg was seen clearly enough to determine the presence or absence of a band), we recorded color-band combinations, territory number, site, standardized confidence levels of the resight, and behavioral observations. Willow flycatchers for which detections spanned one week or longer were considered resident at a site, regardless of the portion of the breeding season in which the bird was observed or whether a possible mate was observed. Flycatchers observed engaging in lengthy, primary song from high perches (male advertising song) were sexed as male, and flycatchers observed carrying nest material or constructing or incubating a nest were sexed as female. Flycatchers not observed engaging in one of these diagnostic activities were sexed as unknown.

Inactive territories were visited at least three times (each visit four days apart) before territory visits stopped. All territories were assigned a unique alphanumeric code and were plotted onto high-resolution aerial photographs, thus producing a spatial representation of the flycatcher population at each study location. Flycatchers were determined to be unpaired if none of the following breeding behaviors were observed: presence of another unchallenged flycatcher in the immediate vicinity, counter calling (***whitts***) with a nearby flycatcher, interaction twitter calls (***churr/kitters***) with a nearby flycatcher, a flycatcher in the immediate vicinity carrying nesting material, a flycatcher in the immediate vicinity carrying food or fecal sac, or adult flycatchers feeding young (per Sogge et al. 1997).

Unbanded flycatchers could not be identified to individual, but an unbanded flycatcher detected in a given location on multiple, consecutive visits was assumed to be the same individual. If an unbanded flycatcher was detected at a given location on multiple visits but one or more intervening visits failed to detect a flycatcher, the detections were considered to be different individuals in the absence of behavioral observations indicating the flycatcher was actively defending a territory or was a member of a breeding pair.

RESULTS

All Monitoring Sites

Color-Banding and Resighting – Field personnel color-banded 18 new adult flycatchers and recaptured 6 individuals previously captured as adults. An additional 50 adults were identified to individual via resighting, while 4 individuals were resighted but did not have their color combinations confirmed, and 1 individual had federal band on one leg and an injury on the other leg. We detected 14 individuals identified as returning nestlings by the presence of a single federal band, with 4 (29%) identified to individual via recapture. Twenty-five adult flycatchers remained unbanded, and banding status was undetermined (i.e., we were unable to determine if these individuals were banded) for 17 adults. Overall, 69% of the adult flycatchers detected at the monitoring sites were known to be color-banded by the end of the breeding season (Table 3.1). We banded 74 nestlings from 29 nests. Of the 74 nestlings banded, 4 were known or suspected to have died before fledging. For details on all banded flycatchers detected at the study areas from 2003 to 2008, see Appendix D.

Site-by-Site Color-Banding and Resighting

Monitoring Sites

Pahranagat – We detected 24 resident, adult willow flycatchers from 17 territories at Pahranagat. In addition to resident adults, we detected two individuals for which residency and/or breeding status could not be confirmed (Table 3.2). Of the 17 territories recorded at Pahranagat, 9 consisted of breeding pairs and 8 consisted of unpaired males. Of the breeding individuals, two males were polygynous with two females.

Field personnel captured and color-banded three new adults and recaptured one flycatcher previously captured as an adult. We resighted and confirmed band combinations for an additional 16 adults. We recaptured two individuals originally banded as nestlings in 2005; both were unpaired males (see Table 3.6 for juvenile dispersal data). Two adults had bands but the combination could not be confirmed, and the presence of bands could not be determined for one adult. Of all the adults detected, one, for which residency and/or breeding status could not be confirmed, remained unbanded. We banded 19 nestlings from six nests. Of the banded nestlings, one was suspected to have died before fledging. We resighted four unbanded fledglings from two additional nests.

Littlefield – We detected one willow flycatcher at Littlefield. This individual was unbanded, and residency and breeding status could not be confirmed (Table 3.2).

Mesquite – We detected 24 resident, adult willow flycatchers from 14 territories at Mesquite. In addition to resident adults, we detected three individuals for which residency and/or breeding status could not be determined. Of the 14 territories recorded at Mesquite, 11 consisted of paired individuals and 3 consisted of unpaired males (Table 3.2). Of the breeding individuals, one male was polygynous with two females.

Field personnel captured and color-banded one new adult flycatcher and recaptured one flycatcher previously captured as an adult. We confirmed the identities of an additional 15 adults via resighting. One additional adult had a federal band on one leg and an injury on the opposite leg. We captured one returning nestling that was originally banded as a juvenile in 2006 and resighted another returning nestling for which study area and year banded could not be determined because we were unable to recapture this individual. Three additional resident adults remained unbanded, and band status could not be determined for two. Band status could also not be determined for two individuals for which residency

and/or breeding status could not be confirmed. We banded 20 nestlings from eight nests; two of these nestlings were suspected to have died before fledging. We resighted one unbanded fledgling from a ninth nest.

Mormon Mesa – We detected 26 resident, adult willow flycatchers from 17 territories at Mormon Mesa. In addition to resident adults, we detected four individuals for which residency could not be confirmed (Table 3.2). Of the 17 territories recorded at Mormon Mesa, 13 consisted of breeding individuals and 4 consisted of unpaired males. Of the resident individuals, one female nested at Virgin River #2 and then moved to Muddy River where she had a second nesting attempt. Of the breeding individuals, four males were each polygynous with two females.

Field personnel captured and color-banded four new adults and recaptured two flycatchers previously captured as adults. We resighted and identified 13 additional returning adults. We captured one returning nestling originally banded as a juvenile in 2007 and resighted an additional three returning nestlings that we were unable to recapture Six adults remained unbanded, and the band status of one individual, for which residency could not be confirmed, was undetermined. We banded 23 nestlings from nine nests. One of these nestlings was known to have died before fledging.

Muddy River – We detected eight resident, adult willow flycatchers from six territories at Muddy River. In addition to resident adults, we detected three individuals for which residency could not be confirmed. Of the six territories recorded, four consisted of breeding individuals and two consisted of unpaired males (Table 3.2). Of the resident individuals, one female nested at Mormon Mesa earlier in the season. Of the breeding individuals, one male was polygynous with three females.

Field personnel captured and color-banded two new adults and recaptured two individuals previously captured as adults. We resighted and identified two other adults and resighted one adult for which band combination could not be confirmed. We resighted one returning nestling but could not capture this individual to determine year and study area of origin. Three adults remained unbanded. We banded three nestlings from one nest and resighted one unbanded fledgling from another nest.

Grand Canyon – We detected one resident, adult willow flycatcher at Iceberg Canyon on the Lake Mead Delta (Table 3.2). Field personnel captured and color-banded this new adult.

Topock – We detected 20 resident, adult willow flycatchers from 12 territories at Topock. In addition to resident adults, we detected 10 individuals for which residency and/or breeding status could not be confirmed (Table 3.2). Five of these individuals were detected for only one day in mid- to late May or early June and were suspected to be migrants. Of the 12 territories recorded at Topock, 9 consisted of paired individuals and 3 consisted of unpaired males. Of the breeding individuals, one male was consecutively polygynous with two females.

Field personnel captured and color-banded three new adults. We resighted and identified four other banded adults. We resighted five returning nestlings but were unable to capture these individuals to determine their identity. The band status of one resident individual could not be determined, and seven resident individuals remained unbanded. Eight of the ten individuals for which residency and/or breeding status could not be confirmed were of unknown band status and two were unbanded. We banded three nestlings from two nests.

Table 3.1. Summary of Willow Flycatchers Detected at Monitored Sites during the 2008 Breeding Season*

* Individuals are identified as new captures (previously unbanded), recaptures of previously banded birds, resightings of previously banded birds for which band combinations were confirmed, birds known to be unbanded, birds for which band status could not be determined, and resighting of previously banded birds for which band combinations were undetermined. Included are total numbers of adults detected and percent of all adults banded. For breeding and/or residency status of adults see Tables 3.2–3.16.

[1] One individual had silver federal band only and had a visible injury on the unbanded left leg; a male with silver federal band number 2390-92434 and a visible injury on the unbanded left leg was captured at Mesquite in 2005, and this is likely the same individual. Other individual was a returning nestling.

[2] Returning nestling(s).

[3] One individual moved from Mormon Mesa Virgin River #2 to Muddy River Overton WMA.

[4] The individual that moved between study areas is tallied only once in the total.

[5] Not a formal survey site. Flycatchers detected en route.

	Deer Island	INA	INA	undetermined	N/A	AHY	U	F3	Detected 21–24 May

[1] PAHR = Pahranagat NWR, LIFI = Littlefield, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, GRCA = Grand Canyon, TOPO = Topock Marsh, BIWI = Bill Williams River NWR, AHAK = Ahakhav Tribal Preserve.

[2] N/A = not applicable, INA = information not available.

[3] **Color-band codes**: EE = electric yellow federal band, PU = pumpkin federal band, Bs = blue federal band, XX = standard silver federal band, (M) = metal pin striped band, UB = unbanded, R = red, O = orange, Y = yellow, G = green, D = dark blue, B = light blue, V = violet, W = white, K = black, Z = gold, banded = bird was banded but combination could not be determined, undetermined = presence of bands could not be determined. Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band; color-band designations for right and left legs are separated with a colon.

[4] Old combination included only if rebanded in 2008.

[5] **Age in 2008**: L = nestling, HY = hatch year, SY = 2 years, AHY = 2 years or older, 3Y = 3 years, A3Y = 3 years or older, 4Y = 4 years, A4Y = 4 years or older, etc.

[6] **Sex codes**: M = male, F = female, U = unknown.

[7] **Territory or Location code**: Number without an alpha code indicates a flycatcher pair, T = territorial individual detected for at least 7 days, F = individual detected for less than 7 days. Number indicates unique location.

[8] **Observation status codes**: N = new capture, R = recapture followed by date recaptured, RS = resight.

[9] One of these four nestlings suspected to have died before fledging.

[10] This female was resighted missing her left foot. Former band combination is EE:DW(M), federal band number 2320-31661.

[11] One of the nestlings suspected to have died before fledging.

[12] Band number likely 2390-92434 but cannot be confirmed because bird was not captured in 2008. Bird had a visible injury on left leg.

[13] This band was removed.

[14] Nestling died before fledging.

[15] Not a formal survey site.

Bill Williams – We detected seven resident willow flycatchers from four territories at Bill Williams. In addition to resident adults, we detected one individual for which residency and/or breeding status could not be determined (Table 3.2). All four territories recorded at Bill Williams consisted of paired individuals. Of the breeding individuals, one male was polygynous with two females.

Field personnel captured and color-banded four new adults. We resighted and identified one returning banded adult, and resighted one additional banded adult but could not confirm the color combination. One resident adult remained unbanded, and band status could not be determined for one adult for which residency status could not be determined. We banded six nestlings from three nests.

Ahakhav Tribal Preserve – We detected one resident willow flycatcher and one individual for which residency could not be determined (Table 3.2). The resident flycatcher was unbanded, and band status could not be determined for the other adult.

Non-Monitoring Sites

These study areas were monitored by other agencies, and here we report only banded flycatchers that were captured or resighted. Unbanded individuals or those with unknown band status are not included.

Key Pittman Wildlife Management Area – Field personnel captured and color-banded nine new adults (Table 3.3). An additional adult was captured with a single federal band; this individual had been captured but not rebanded previously as an adult. We resighted and identified four returning banded adults. We recaptured two returning nestlings, one each from 2006 and 2007 (see Table 3.6 for juvenile dispersal data). We banded six nestlings from two nests.

St. George – Field personnel resighted and identified one adult flycatcher. A second adult was identified as a returning nestling, but we were unable to capture this individual to determine year and study area of origin. We banded five nestlings from two nests (Table 3.3).

Las Vegas Wash – Field personnel captured and color-banded one adult (Table 3.3).

[5] **Sex codes**: M = male, F = female, U = unknown.

[6] **Observation status codes**: N = new capture, R = recapture followed by date recaptured, RS = resight.

Adult Between-Year Return and Dispersal

In 2007 we identified 95 adult, resident willow flycatchers at our monitored study areas, of which 54 (57%) were detected in 2008 (Table 3.4). Of the returning adults, three (6%) were detected at a different study area than where they were last detected in 2007, and two of those were detected at study areas (Key Pittman and St. George) monitored by other agencies (Table 3.5). Two additional adults, one of which was last detected in 2005 and the other in 2006, exhibited between-year movement in 2008. The median dispersal distance for all returning adult flycatchers exhibiting between-year movements in 2008 was 32 km (min = 13 km, max = 61 km).

Table 3.4. Resident Adult Willow Flycatcher Annual Return from 2007 to 2008

Study Area	# Identified in 2007	# of 2007 Birds Detected in 2008	% Return	% Return to Same Study Area

Juvenile Between-Year Return and Dispersal

In 2007, we banded 55 nestlings and 1 fledgling at the monitored study areas. Six of these nestlings were known to have died before fledging. Of the 50 remaining juveniles, 2 (4%) were recaptured and identified in 2008. Both were detected at a different study area from where originally banded. Two individuals originally banded as nestlings in 2005 and two banded in 2006 were also recaptured for the first time; of these, three returned to a different study area than where originally banded (Table 3.6). The median dispersal distance for all returning juvenile flycatchers in 2008 was 30 km (min = 0.15 km, max = 30 km).

Table 3.6. Summary of Juvenile Flycatchers Banded as Hatch Year Birds in 2005, 2006, or 2007 and Recaptured for the First Time in 2008

Study Area/ Site Banded	Year Hatched	Study Area/Site Detected 2008	Distance Moved (km)	Federal Band #	Color Combination[2]	Sex[3]

[1] KEPI = Key Pittman WMA, PAHR = Pahranagat NWR, MESQ = Mesquite, MOME = Mormon Mesa.

[2] **Color-band codes**: EE = electric yellow federal band, PU = pumpkin federal band, (M) = metal pin striped band, B = light blue, D = dark blue, G = green, R = red, W = white, K = black. Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band; color-band designations for right and left legs are separated with a colon.

[3] **Sex codes**: F = female, M = male, U = unknown.

Ten additional returning nestlings from 2003–2007 were resighted in 2008 (one each at Mesquite and Muddy River, three at Mormon Mesa, and five at Topock), but the identity of these individuals was undetermined because we were unable to recapture them.

Within-Year, Between-Study Area Movements

We detected two within-year, between study area movements in 2008. One male held a territory at Pahranagat North from 19 May to 11 July and then was detected at Key Pittman on 26 July. A female had an unsuccessful nesting attempt at Mormon Mesa Virgin River #2 (25 May–29 June) and then moved to Muddy River Overton WMA where she had another unsuccessful nesting attempt (14–19 July).

DISCUSSION

Color-Banding Effort

Overall, 69% of the adult flycatchers detected at the monitoring sites during 2008 were banded by the end of the breeding season. This compares to 55, 57, 75, 70, and 73% in 2003–2007, respectively. Unbanded migrant willow flycatchers are included in calculating these percentages; therefore, in most cases, these numbers under-represent the actual proportion of resident banded flycatchers at a given site. We have maintained high overall percentages of banded birds annually over the five years, which has enabled us to detect movements, generate dispersal data, and determine survival and detection probabilities across study areas (McLeod et al. 2008a). Differences between study areas in the percentage of banded individuals are directly related to vegetation density and overall structure, which affect our ability to erect mist-nets in the habitat. Topock Marsh typically has the lowest percentage of color-banded flycatchers because dense vegetation limits the number and size of possible net locations.

Prior to 2008, we banded all nestlings with a single anodized federal band, identifying the bird as a returning nestling in the event it was sighted in a subsequent year. The individual would then have to be recaptured to determine its individual identity and to apply a unique color combination so the bird could be individually identified via resighting. Returning nestlings were particularly difficult to recapture at Topock. To eliminate the need to recapture returning nestlings, in 2008 we applied unique color

combinations to all nestlings. These nestlings will not need to be recaptured in subsequent years, and the use of full color combinations on nestlings should increase the proportion of adults that can be individually identified and yield more information on juvenile dispersal and survivorship.

Adult and Juvenile Between-Year Dispersal

Ninety-four percent of all adults detected in both 2007 and 2008 were detected at the same study area in both years. From 1998 to 2007, 92% of all between-year adult returns were to the same study area. Of the six individuals that were banded as juveniles in 2005–2007 and detected for the first time in 2008, 50% returned to the same study area where originally banded. From 1997 to 2007, 41% of all returning juveniles dispersed away from the natal area (McKernan and Braden unpubl. data, McLeod et al. 2008a). Adult and juvenile dispersal data show high site fidelity exhibited by adult flycatchers and lower natal site fidelity exhibited by juveniles, with juveniles dispersing among study areas annually. These dispersal data are consistent with range-wide data (Paxton et al. 2007), with adult flycatchers exhibiting high site fidelity to breeding areas. Juvenile dispersal within the Virgin/lower Colorado River population(s) is largely limited to this region, and while reciprocal juvenile movements among geographically isolated flycatcher populations of the greater Southwest do occur, they are rare. Only three instances of willow flycatcher immigration from sites outside the Virgin/lower Colorado River region have been recorded since 1997 (McKernan and Braden unpubl. data, McLeod et al. 2008a), with two males originally banded as nestlings in 2003 at Roosevelt Lake recaptured in 2005 at Muddy River and Topock, and one male banded as a nestling in 1999 at Roosevelt Lake recaptured in 2002 in Grand Canyon. Although movements of this magnitude are infrequent, other instances of dispersal distances greater than 140 km have been reported for the Southwestern Willow Flycatcher (Paxton et al. 2007).

The observed dispersal patterns fit well with the tenets of contemporary metapopulation theory (Hanski and Simberloff 1997), suggesting the Virgin/lower Colorado River population may be a panmictic sub-population of a greater metapopulation. Occasional juvenile dispersal between sub-populations is likely an important population variable in terms of both gene flow and possibly the establishment of new flycatcher populations. These juvenile movements contribute to an understanding of the observed patterns of high genetic diversity within and low genetic isolation among Southwestern Willow Flycatcher populations (Busch et al. 2000). Physical connectivity of riparian habitats within the greater landscape is crucial in enabling these long-distance movements. Without adequate stop-over habitats and foraging areas, flycatchers attempting long-distance movements are more likely to be exposed to adverse environmental conditions.

Adult and Juvenile Survivorship

Annual survivorship is defined as the number of individuals that survive from one year to the next, and accurate estimates depend on year-to-year detection of uniquely marked birds. Fifty-seven percent of the adult, resident willow flycatchers identified in 2007 were detected again in 2008, while of the 50 juveniles banded in 2007, only 2 (4%) were identified in 2008. Thus, minimum estimated adult and juvenile survival from 2007 to 2008 was 57 and 4%, respectively. These simple annual percent survivorship calculations assume that all living flycatchers are detected in a given year, and individuals not detected are assumed to have died, unless detected elsewhere. This is the lowest juvenile return rate recorded since 2004, with an average return rate of 13% recorded in 2004–2007 for the juveniles from the previous year. Flycatchers sometimes go undetected for up to three years after being banded as juveniles, and banding data collected in future years will determine if low survival rates, low detection rates, or both contributed to the low number of juveniles from 2007 identified in 2008.

Chapter 4

NEST MONITORING

INTRODUCTION

Documentation of nest success and productivity is critical to understanding local population status and demographic patterns of the Southwestern Willow Flycatcher. In 2008, at all sites where willow flycatcher breeding activity was suspected, we conducted intensive nest searches and nest monitoring. Specific objectives of nest monitoring included identifying breeding individuals (see Chapter 3, Color-banding and Resighting), calculating nest success and failure, documenting causes of nest failure (e.g., abandonment, desertion, depredation, and brood parasitism), and calculating nest productivity. Nest monitoring results from 2008 were compared with those at the study areas from 1996 to 2007 (Braden and McKernan unpubl. data, McLeod et al. 2008a). Although aspects of willow flycatcher breeding ecology can vary widely across its broad geographical and elevational ranges throughout the Southwest (Whitfield et al. 2003), we compared monitoring results with range-wide data to identify specific variables that may contribute to the characterization of flycatcher breeding ecology throughout the lower Colorado and Virgin River riparian systems.

METHODS

Upon locating territorial willow flycatchers, regardless of whether a possible mate was observed, we conducted intensive nest searches following the methods of Rourke et al. (1999). Nest monitoring followed a modification of the methods described by Rourke et al. (1999) and the Breeding Biology Research and Monitoring Database (BBIRD) protocol by Martin et al. (1997).

Nests were located primarily by observing adult flycatchers return to a nest or by systematically searching suspected nest sites. Nests were monitored every two to four days after nest building was complete and incubation was confirmed. During incubation and after hatching, nest contents were observed directly using a telescoping mirror pole to determine nest contents and transition dates. Nest monitoring during nest building and egg laying stages was limited to reduce the chance of abandonment during these periods. To reduce the risk of depredation (Martin et al. 1997), brood parasitism by the Brown-headed Cowbird, and premature fledging of young (Rourke et al. 1999), we observed nests from a distance with binoculars once the number and age of nestlings were confirmed. If no activity was observed at a previously occupied nest, the nest was checked directly to determine nest contents and cause of failure. If no activity was observed at a nest close to or on the estimated fledge date, we conducted a systematic search of the area to locate possible fledglings.

Per instructions from Reclamation biologists, we considered a willow flycatcher nest successful only if fledglings were observed near the nest or in surrounding areas. The number of young fledged from each nest was counted based on the number of fledglings actually observed. This method of determining success differs from that recommended by some nest monitoring protocols (e.g., Martin et al. 1997, Rourke et al. 1999), which consider a nest as successful if chicks are observed in the nest within two days of the estimated fledge date. The method we follow produces a conservative estimate of both nest success rate and number of fledges.

We considered a nest to have failed if (1) the nest was abandoned prior to egg laying (abandoned); (2) the nest was deserted with flycatcher eggs or young remaining (deserted); (3) the nest was found empty or

destroyed more than two days prior to the estimated fledge date (depredated); (4) the nest was destroyed due to weather (weather); or (5) the entire clutch was incubated for an excess of 20 days (infertile/addled). For nests containing flycatcher eggs, parasitism was considered the cause of nest failure if (1) cowbird young outlived any flycatcher eggs or young, or (2) the nest was parasitized during egg laying and the disappearance of flycatcher eggs coincided with the appearance of cowbird eggs.

During each nest check, we recorded date and time of the visit, observer initials, monitoring method (observation via binoculars or mirror pole), nesting stage, nest contents, and number and behavior of adults and/or fledges present onto standardized data forms (Appendix A) that included the nest or territory number and UTM coordinates. We calculated flycatcher nest success using both simple nesting success (number of successful nests/total number of nests containing at least one flycatcher egg) and the Mayfield method (Mayfield 1961, 1975), which calculates daily nest survival to account for nests that failed before they were found. We assumed one egg was laid per day, and incubation was considered to start the day the last egg was laid (per Martin et al. 1997). The nestling period was considered to start the day the first egg hatched and end the day the first nestling fledged. If exact transition dates or dates of depredation events were unknown, we estimated the transition date as halfway between observations. For nests where fate was unknown, we used the last known date of activity to determine the number of observation days. To calculate Mayfield survival probabilities (MSP), we used the average length of each nest stage (2.12, 12.90, and 13.71 days for laying, incubation, and nestling stages, respectively) as observed in this study in 2003–2008 for nests where transition dates were known. Nest productivity was calculated as the number of young fledged per nesting attempt that produced at least one flycatcher egg. Fecundity was calculated as number of young produced per female over the breeding season. Parasitism rates were calculated as the number of nests that contained at least one cowbird egg/number of nests containing at least one flycatcher egg and having known contents.

RESULTS

Nest Monitoring

We documented 62 willow flycatcher nesting attempts at Pahranagat, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams; 55 of these nests were known to contain flycatcher eggs and were used in calculating nest success and productivity. Thirty (55%) nests were successful and fledged young, 23 (42%) failed, and fate was unknown for 2 (3%). Nest success ranged from 13% at Topock Marsh to 82% at Mesquite (Table 4.1). For a comparison of nest success at all monitoring sites from 1997 to 2008, see Table 4.2.

[1] PAHR = Pahranagat NWR, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR.

[2] WE = willow flycatcher egg.

[3] Only nests with at least one flycatcher egg were used in percentage calculations. Percentages are given in parentheses.

[4] Parasitized nests include all nests that contained at least one flycatcher egg and one cowbird egg, regardless of nest fate. Percentages include only nests with at least one flycatcher egg and for which contents could be determined.

Forty-eight nesting females, of which all but three were known to have produced at least one egg, were followed through all of their nesting attempts. One additional female was detected for which no nesting attempt could be confirmed. Of the 48 nesting females, 36 had one nesting attempt, 10 had two nesting attempts, and 2 had three nesting attempts. All 12 females who had multiple nesting attempts renested after unsuccessful nests.

* Data from 1997 to 2002 are from Braden and McKernan (unpubl. data); these numbers have been verified with the raw data and may differ from those presented in earlier annual reports. Data from 2003 to 2007 are from McLeod et al. 2008a, and data from 2008 can be found in this document. Total number of nests containing at least one flycatcher egg is indicated in parentheses.

[1] Study area includes the Mesquite East, Mesquite West, and Bunker Farm sites.

[2] Study area includes the Virgin River Delta at Lake Mead.

[3] Study area not monitored.

[4] Study area surveyed, no breeding documented.

[5] Breeding suspected, nest success not calculated.

[6] Breeding confirmed, nest success not calculated.

[7] Breeding confirmed, undetermined if nestlings from a single nest fledged.

[8] An additional three nests (18%) were suspected to have fledged but fledglings were not visually confirmed.

[9] Fate of one nest was unknown.

Nest Failure

Depredation was the major cause of nest failure, accounting for 40% (12 of 30) of all failed nests (Table 4.3) and 52% (15 of 23) of nests that failed after flycatcher eggs were laid. Seven nesting attempts (23% of all failed nests) were abandoned prior to willow flycatcher eggs being laid and nine nests (30%) were deserted. Two nests (7%) failed because of Brown-headed Cowbird parasitism (see below for more details on parasitism).

Table 4.3. Summary of Causes of Willow Flycatcher Nest Failure at Pahranagat, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams Study Areas, 2008*

Study Area[1]	Total # Nests	All Failed Nests	Abandoned	Deserted	Depredated	Parasitized
PAHR	12	4	2 (50)	0	2 (50)	0
MESQ	11	2	0	1 (50)[2]	1 (50)	0
MOME	14	6	1 (17)	3 (50)[3]	1 (17)	1 (17)

TOPO	12	10	4 (10)	2 (20)[5]	4 (40)	0
BIWI	5	2	0	2 (100)[6]	0	0
Total	**62**	**30**	**7 (23)**	**9 (30)**	**12 (40)**	**2 (7)**

* All nesting attempts (those with and without flycatcher eggs) are included. Percentage of failed nests is shown in parentheses for each cause of failure.

[1] PAHR = Pahranagat NWR, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR.

[2] Nest deserted during incubation.

[3] One nest deserted after 18 days incubation, one nest already deserted when found, one nest deserted during laying.

[4] Nest deserted after being parasitized.

[5] One nest deserted during laying, one nest deserted after at least 20 days incubation.

[6] One nest deserted after video camera was set up at nest, one nest deserted during incubation.

Brood Parasitism

Eight of 48[1] nests (17%) with flycatcher eggs and known contents were brood parasitized by Brown-headed Cowbirds (Table 4.4). For nests containing flycatcher eggs, parasitism caused nest failure at two nests. In one case, the nest was parasitized during laying, and appearance of the cowbird egg coincided with disappearance of the flycatcher egg. In the other case, the nest fledged a cowbird and the severely underdeveloped flycatcher nestling was found dead under the nest. One parasitized nest fledged a flycatcher but no cowbirds, and two nests fledged both a cowbird and a flycatcher. Two parasitized nests were depredated during incubation, and one nest was deserted after at least 20 days incubation. Brood parasitism ranged from 0 to 57% and was highest at Muddy River (see Table 4.1). In 2008, three of eight (38%) parasitized nests successfully fledged flycatchers, and nests that contained flycatcher eggs and were brood parasitized were not less likely to fledge flycatcher young than nests that were not parasitized (Chi-square = 1.10, $P = 0.293$). However, when data were pooled for all years from 2003 to 2008 to obtain a larger sample size and greater statistical power, parasitized nests were less likely to fledge flycatcher young, with 18 of 80 (23%) parasitized nests fledging flycatcher young vs. 148 of 284 (52%) non-parasitized nests (Chi-square = 22.06, . $P < 0.001$). In addition, parasitized nests that did succeed in fledging flycatcher young produced on average fewer fledges (1.2 per nest) than non-parasitized nests (2.2 fledges per nest; $F_{1,164} = 19.0$, $P < 0.001$). From 2003 to 2008, 7 of 17 nests that fledged cowbirds also fledged flycatcher young.

Table 4.4. Fates of Willow Flycatcher Nests Parasitized by Brown-Headed Cowbirds, 2008*

Study Area[1]	Nest ID Code	Outcome[2]
MESQ	21A	Fledged one cowbird and one flycatcher
MOME	65B	Parasitized during laying; fledged one cowbird; flycatcher nestling found dead under nest
MUDD	1A	Fledged one cowbird and one flycatcher
	1B	Nest depredated during incubation
	1C	Nest depredated during incubation
	20A	Parasitized during laying; WE disappeared and CE appeared; nest abandoned
TOPO	9A	Parasitized after at least 6 days incubation; nest deserted after at least 20 days incubation; no eggs hatched
BIWI	31B	Fledged one flycatcher; CE did not hatch

* All nesting attempts are included.
[1] MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR.
[2] WE = willow flycatcher egg, CE = cowbird egg.

Mayfield Nest Success and Nest Productivity

Mayfield survival probability (MSP) ranged from 0.194 at Muddy River to 0.705 at Mesquite and was 0.461 for all sites combined (Table 4.5). At all sites, 66 nestlings were confirmed to have fledged from 53 nests of known outcome (mean number of nestlings/nest = 1.25, SE = 0.17). Fecundity across study areas ranged from 0.13 to 2.33 young per female and averaged 1.40 (SE = 0.18) (Table 4.6).

[1] Table 4.1 shows a total of 55 nests known to contain at least one flycatcher egg. When calculating brood parasitism rates, however, seven nests whose contents could not be determined were excluded from calculations (i.e., nests that were too high to check contents to determine presence/absence of cowbird eggs).

Table 4.5. Daily Survival Rates and Mayfield Survival Probabilities (MSP) for Willow Flycatcher Nest Stages at Pahranagat, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams Study Areas, 2008*

Table 4.6. Willow Flycatcher Nest Productivity (Young Fledged per Nest) and Fecundity (Young Fledged per Female) at Pahranagat, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams Study Areas, 2008*

Study Area	Young Fledged (# Nests)	Productivity Mean (SE)	Fecundity Mean (SE)
Pahranagat	21 (10)	2.10 (0.41)	2.33 (0.37)
Mesquite	18 (11)	1.64 (0.34)	1.64 (0.34)
Mormon Mesa	19 (13)	1.46 (0.37)	1.46 (0.37)
Muddy River	3 (8)	0.38 (0.26)	0.75 (0.48)
Topock	1 (7)	0.14 (0.14)	0.13 (0.13)
Bill Williams	4 (4)	1.00 (0.71)	1.33 (0.88)
Total	**66 (53)**	**1.25 (0.17)**	**1.40 (0.18)[1]**

* Productivity calculations include nests that contained flycatcher eggs and had a known outcome.
[1] The female that moved from Mormon Mesa to Muddy River is counted only once in the total.

DISCUSSION

In 2008, willow flycatcher nesting was documented at Pahranagat, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams. The number of breeding pairs recorded at Pahranagat, Mesquite, Mormon Mesa, and Topock Marsh were consistent with those recorded in 2007. The number of breeding pairs at Bill Williams in 2008 (3) was identical to that recorded in 2006 but less than half the number observed in 2007 (7). Muddy River had the lowest number of breeding pairs recorded since 2005; this decline in breeding activity could be related to recent habitat modifications within the site (see Chapter 2), which may have affected occupancy in the northern portion of the site in 2008. Given that southwestern riparian ecosystems experience dynamic change and are not ecologically static (Periman and Kelly 2000), willow flycatcher occupancy and nesting are likely to be affected by changes in habitat suitability, with breeding flycatchers detected at a given site in one year and not in another.

Nest Success

As in 2003–2007, Pahranagat continued to exhibit high nest success. Nest success at Mesquite was the highest observed since monitoring began in 1997, and nest success at Mormon Mesa was the highest recorded since 1998. Nest success at Topock Marsh, however, was the lowest ever recorded. Nest success at the remaining study areas continued to exhibit the yearly fluctuations observed since nest monitoring began in 1996. Nest success results again illustrate that the demographic patterns of passerine populations often vary year to year, and sometimes to a very large degree (Wiens 1989a). The variable patterns of nest success observed at the study areas over many years further demonstrate the need for long-term data.

Nest Failure

As in 2003–2007, depredation was the major cause of willow flycatcher nest failure, accounting for 40% of all failed nests in 2008 (see Table 4.3). These results are consistent with those reported at the life history study areas from 1998 to 2007 (Braden and McKernan unpubl. data, McLeod et al. 2008a) and at monitored sites across Arizona from 2000 to 2006 (Paradzick et al. 2001; Smith et al. 2002, 2003, 2004; Munzer et al. 2005; English et al. 2006; Graber et al. 2007; Ellis et al. 2008), which indicate depredation as accounting for the majority of all willow flycatcher nest failures. Factors influencing the increases and decreases in nest depredation at the life history study areas are inherently complex and at this time remain undetermined. For open-cup nesting passerines, it has been shown that nest depredation rates can vary year to year, and sometimes substantially, with depredation of eggs and young ultimately linked to landscape characteristics and fluctuations in predator densities, abundance, and richness (Wiens 1989b, Robinson 1992, Howlett and Stutchbury 1996).

In 2008, Northern Arizona University (NAU) initiated a nest camera study in cooperation with SWCA on open-cup nesting passerines at selected study areas along the lower Colorado River and tributaries. The study used video and still cameras on real and artificial nests to identify depredation rates and nest predators. Problems with both video and still cameras affected the detection of depredation events and the identification of nest predators, but both Brown-headed Cowbirds and Yellow-breasted Chats were identified by still cameras as depredating artificial nests (NAU unpubl. data). Ellis et al. (2008) also identified Yellow-breasted Chats depredating flycatcher nests at sites in Arizona. The camera study will be continued in 2009 and may provide additional information on the identity and relative importance of nest predators.

Brood Parasitism

Brood parasitism by Brown-headed Cowbirds across all study areas ranged from 0 to 57% and averaged 17% (see Table 4.1). These results are consistent with those reported at the study areas from 1998 to 2007 (Braden and McKernan unpubl. data, McLeod et al. 2008a), but these parasitism rates are higher than those reported at monitored sites across Arizona, which averaged 4, 5, 11, 2, 6, 7, and 13% in 2000, 2001, 2002, 2003, 2004, 2005, and 2006, respectively (Paradzick et al. 2001; Smith et al. 2002, 2003, 2004; Munzer et al. 2005; English et al. 2006; Graber et al. 2007). We observed the sixth consecutive year of no brood parasitism at Pahranagat, and Mesquite experienced the lowest parasitism rate recorded since 2003. Muddy River continued to have high parasitism rates.

Cowbird trapping and removal studies were initiated at Pahranagat, Mesquite, and Topock Marsh in 2003 and continued through 2007. Results of these studies showed that cowbird trapping appeared to lower parasitism rates in comparison to the pre-trapping period of 1998–2002 only at Pahranagat, with no parasitism detected during trapping years (McLeod et al. 2008a). No cowbird trapping was completed in 2008, the first year of a planned five-year post-trapping monitoring period. Even in the absence of cowbird trapping, no parasitism events were detected at Pahranagat in 2008. This suggests that cowbird trapping may have lingering effects beyond the years in which trapping is completed, though a single year of data at one study area is insufficient to draw strong conclusions.

We observed one occasion in which the disappearance of flycatcher eggs coincided with the parasitism event. In this case, cowbirds were suspected of ejecting the eggs. Female Brown-headed Cowbirds are known to physically attack willow flycatcher nestlings (Woodward and Stoleson 2002), remove single eggs, and occasionally destroy entire broods after laying is complete or after hatching (Lowther 1993 as cited in Woodward and Stoleson 2002), and cowbirds were photographed removing eggs from artificial nests during the 2008 camera study. Therefore, it is likely that some depredation events on eggs and nestlings are attributable to cowbirds.

Parasitism does not invariably cause nest failure, but the success rate for parasitized nests in 2003–2008 was less than half that of unparasitized nests. A similar result was recorded for willow flycatchers in Oregon, with parasitism resulting in a 50% decrease in success rates compared to unparasitized nests (Sedgwick and Iko 1999). Parasitized nests that do succeed in fledging flycatcher young produced on average fewer young than unparasitized nests; cowbirds may eject flycatcher eggs during the parasitism event, thus reducing clutch size, and cowbird young also cause interspecific nestling competition, as evidenced by the presence of severely underdeveloped nestlings in parasitized nests. For all nests monitored from 2003 to 2008, 41% of nests that fledged a cowbird also fledged flycatcher young. This is a higher rate of success than that observed in other Southwestern Willow Flycatcher populations, with 9% and 0% reported for the Kern River, California, and various Arizona sites, respectively (Whitfield and Sogge 1999).

Female flycatchers may desert their nests after parasitism events and thus expend energy renesting and laying additional eggs. Given that adult flycatchers exhibit high site fidelity to breeding areas (Braden and McKernan unpubl. data, McLeod et al. 2008a, this document) and renest most often after failed nests (Sedgwick 2000), females returning to sites with high brood parasitism are likely to reduce lifetime fecundity because they are expending energy on multiple failed nesting attempts over many years. In addition, willow flycatchers that fledge late in the season have been shown to have a lower survival rate than those that fledge early in the season (Paxton et al. 2007, McLeod et al. 2008a), suggesting additional hidden effects of parasitism and subsequent renesting on flycatcher demography.

Mayfield Nest Success and Nest Productivity

Overall MSP in 2008 (0.461) was nearly identical to that recorded in 2007 (0.459), though the relative contributions of various study areas to overall MSP differed between years. MSP alone, however, is an incomplete measure of the production of young. Successful nests produce from one to four young, and variations in nest productivity are not reflected in MSP. In addition, although every failed nest attempt lowers percent nest success and MSP, success of a subsequent nesting attempt may result in the same number of young produced as if the initial nesting attempt had been successful. Thus, nest productivity (young produced per nesting attempt) and fecundity (young produced per female), in conjunction with nest success, provide additional information on the success of a given breeding season. Overall fecundity in 2008 (1.40) did not differ statistically from that recorded in 2003–2007 ($F_{5,308} = 0.916$, $P = 0.47$).

Chapter 5

VEGETATION AND HABITAT CHARACTERISTICS

INTRODUCTION

Our objective for vegetation sampling is to provide a quantitative summary of the floristic and structural conditions within occupied territories in various vegetation types. These descriptive summaries will provide guidance for managers working to restore and create riparian habitat to meet the obligations of the LCR MSCP and will provide a means to evaluate habitats to determine if they resemble occupied flycatcher territories. The Pahranagat study area was excluded from the characterization of occupied territories because the vegetation consists primarily of very large and widely spaces trees, and these characteristics are unique to the site and not likely to be replicated in restoration areas.

In addition, we investigated whether changes in vegetation characteristics might have contributed to the abandonment of some areas by flycatchers. We identified several areas that had been occupied by nesting flycatchers in at least one previous year from 2003 to 2007 but were unoccupied in 2008, and we relocated old nest sites at which we had collected vegetation information in the year the nest was active. We resampled the vegetation at these nests and compared the vegetation data collected in 2008 to that collected when the nest site was active to elucidate how changes in vegetation through time may influence flycatcher occupancy. These results will provide additional quantitative information on the characteristics of vegetation within flycatcher nesting territories.

METHODS

Currently Occupied Territories

We described and measured vegetation and habitat features following a modification of the methods of James and Shugart (1970). Vegetation characteristics were measured within a 5-m-radius circle. To avoid disrupting flycatcher breeding activities, we measured vegetation late in the summer when the nest, territory, and adjacent flycatcher territories were inactive.

We measured vegetation and habitat characteristics at one plot for each resident (i.e., detected for at least one week) male flycatcher we identified, regardless of whether or not he obtained a mate. Plot center locations were determined as soon as territories were identified. We estimated the center of the male's activity by observing his use of singing perches and selecting a location that was approximately equidistant from the perches at the perimeter of his use area. We then proceeded in a randomly selected compass direction for a randomly selected distance between 0 and 20 m. We used additional random numbers to select the exact location in which to hang a temperature/humidity data logger (see Chapter 6) and used that location as plot center. This process resulted in the random selection of a point that was still within the male's territory.

At each plot, we laid out four 5-m-long ropes from plot center, one in each of the four cardinal directions. Each rope was marked at 1 m and 5 m from the center of the plot. At plot center and at 1 m and 5 m from the center of the plot in each cardinal direction, we measured vertical foliage density using a 7.5-m-tall survey rod. Working our way up the rod, we recorded the presence of vegetation, by species, within a 10-cm radius of the rod in 0.1-m intervals (presence of the species within the 0.1-m interval equaled one "hit" on the rod), and summed all hits in 1-m intervals. Presence of dead vegetation (snags) was recorded

in the same manner, but not identified to species. If canopy vegetation continued above 8.0 m, we estimated the number of hits as zero, greater than five, or less than five hits per 1-m interval until the canopy vegetation stopped (modified from Rotenberry 1985).

We measured total canopy closure using a Model-A spherical densiometer at 1 m north and south of the center of each plot and averaged these measurements to obtain a single canopy closure value for each plot. We measured average canopy height within each plot by selecting a representative tree and using a survey rod or a clinometer and measuring tape to measure the height of the selected tree. We estimated percent woody ground cover, alive and dead, within 0.5 m of the ground using a Daubenmire-type frame with the lower edge of the frame centered at 1 m north, south, east, and west of plot center. These percentages were averaged to obtain a single measure of percent woody ground cover for each plot.

We tallied the number of live stems for each species within 5 m of the center of the plot. Stems were tallied if they were at least 1.4-m tall and >2.5 cm in diameter at 10 cm above the ground. Stems were tallied by the following diameter at breast height (dbh) categories: <1 cm, 1–2.5 cm, 2.6–5.5 cm, 5.6–8 cm, 8.1–10.5 cm, and 10.5–15 cm. Any stems >15 cm dbh were measured and the exact dbh was recorded. Dead stems were also tallied in these categories, but not identified to species. In previous years of vegetation sampling, if a stem branched above 10 cm but below 1.4 m above the ground, only the largest stem was tallied. In habitats (e.g., tamarisk) where stems frequently branch in this height interval, this method of counting stems may underestimate the density of stems that form an important part of the habitat structure. Therefore, in 2008 we tallied stems as we had in previous years and then for each stem that branched between 10 cm and 1.4 m from the ground, we tallied the number of additional stems that were at least 2.5 cm in diameter at 10 cm above the point where it branched from the main stem.

Additional information recorded at each plot included the date when the measurements were taken, observer initials, and UTM coordinates for each plot center.

Several habitat variables that were measured in previous years were not measured in 2008 because they were not useful in differentiating habitats or because logistical difficulties precluded accurate data collection. These variables were distance to canopy gap, distance to broadleaf tree, distance to water, and number of stems >8 cm dbh between 5 and 11.3 m of plot center.

Nests in Formerly Occupied Areas

The same measurements that were completed at occupied territories were also taken at old nest sites. We used the UTM coordinates of the nest, nest tree species, nest height, and nest flags that remained in the field to locate the old nests. Vegetation plots were centered on the nest location.

Data Analyses

We used high-resolution aerial photography and field knowledge of each study area to delineate clusters of territories that occur within habitat patches of similar floristics and canopy height. Vegetation characteristics were then summarized for each habitat type. We used SPSS® Version 16.0 (SPSS Inc.) software for statistical analyses. Data presented are means ± standard error (SE) unless otherwise stated.

Stem counts were grouped into the following size categories for analysis: <2.5 cm dbh, 2.5–8 cm dbh, and >8 cm dbh. For each size category, stem counts are reported separately for live and dead stems; the sum of these is the equivalent of the stem counts per size category that were reported in the 2003–2007 summary report (McLeod et al. 2008a). Vertical foliage density measurements above 8.0 m that were recorded as < or >5 hits per meter were converted to 2.5 and 7.5 hits, respectively, to allow analyses of

these data as continuous rather than categorical. Vertical foliage density was calculated for each meter interval as the mean of the number of hits recorded within the interval at the nine locations in the plot. In previous years, we had measured vertical foliage density only at plot center and 1 m from plot center in each cardinal direction, and foliage density measures per meter interval were presented as the sum of the hits recorded at the five locations in the plot. Thus, vertical foliage data presented in previous reports should be divided by 5 to be comparable to data presented here. In the five-year summary report (McLeod et al. 2008a), vertical foliage data were grouped into three categories of above, at, and below the nest. Vegetation data were not collected at nest sites in 2008, so we used average nest height as measured in 2003–2007 in each vegetation type to demarcate vertical foliage categories. As with stem counts, vertical foliage data are reported separately for live and dead vegetation.

Percent native vegetation was calculated as the average of the percent basal area that was native and the percent native vertical foliage hits. For data collected in 2003–2007 and reported in McLeod et al. 2008a), we did not use vertical foliage data to calculate percent native because all vertical foliage data were collected within 1 m of plot center and represented only a small portion of the plot. We included vertical foliage data in the percent native calculations in 2008 to account for the influence of stems that were too small to be tallied or were rooted outside the 5-m-radius circle but overhung the plot. All exotic vegetation consisted of tamarisk.

We used non-parametric Wilcoxon signed rank tests for related samples to compare vegetation measurements collected at old nests to the measurements collected during the year the nest was active. We chose non-parametric tests because several parameters had non-normal distributions. Vertical foliage data used in these comparisons were restricted to data collected within 1 m of plot center so as to be directly comparable to data collected prior to 2008. A statistical significance level of $P \leq 0.05$ was chosen to reject null hypotheses.

RESULTS

Currently Occupied Territories

We measured vegetation at 41 occupied territories at Mesquite, Mormon Mesa, Muddy River, Topock Marsh, Bill Williams, and Ahakhav. We delineated the following habitat types: 1) coyote willow, 2) tamarisk/coyote willow mix, 3) Goodding willow, 4) Goodding willow with tamarisk understory, 5) tamarisk with scattered Goodding willow, 6) tamarisk, and 7) tamarisk/mesquite mix. Coyote willow and tamarisk/coyote willow mix occurred only at Mesquite, with coyote willow dominating the eastern half of the site while tamarisk and coyote willow were mixed in the western half of the site. Goodding willow occurred in the southern portion of Muddy River, in a small stand readily discernible on high-resolution aerial photographs. Large Goodding willow with tamarisk understory occurred at Bill Williams. Tamarisk with scattered, emergent Goodding willow occurred both at Mormon Mesa and Topock; these two study areas were summarized separately because several variables, including canopy height and canopy closure, differed between the two areas. Tamarisk habitats lacking emergent willows occurred both at Muddy River and Topock, while tamarisk with mesquite occurred at Ahakhav. Average nest height recorded in 2003–2007 and used to assign vertical foliage strata for each vegetation category were 2.0, 2.4, 2.4, 4.5, 2.6, 3.4, and 4.0 m for coyote willow, tamarisk/coyote willow mix, Goodding willow, Goodding willow with tamarisk understory, tamarisk with scattered Goodding willow at Mormon Mesa, tamarisk with scattered Goodding willow at Topock, and tamarisk, respectively. No nests were known from tamarisk/mesquite habitat, so the overall mean nest height of 3.2 m was used to assign vertical foliage categories for that vegetation type.

Vegetation characteristics of each habitat type are summarized in Table 5.1. Habitat types varied widely in many characteristics, and plots within each habitat type also showed a wide range in most habitat variables.

The proportion of stems omitted from stem counts by counting only the largest stem of a cluster that branched between 10 cm and 1.4 m above the ground varied both by size and species of the main stem (Table 5.2). Tamarisk had the highest proportion of omitted stems, and larger stems had more branches that were omitted.

Including vertical foliage data in the calculation of percent native had, overall, little effect when compared to percent native as calculated solely from basal area. For plots that were <25% native by basal area (21 of 41 plots), including vertical foliage in the calculations increased percent native by an average of 5.5% (median 1.0%). This was generally because for some plots, vertical foliage data included large Goodding willow that were rooted outside but overhung the vegetation plot. For plots that were >75% native by basal area (15 of 41 plots), including vertical foliage decreased the percent native by an average of 3.6% (median 1.5%).

Vertical foliage profiles for each habitat type are shown in Figures 5.1–5.8. Average nest height in each habitat type, as recorded in 2003–2007, is also shown on each graph. No nests were recorded in tamarisk-mesquite habitat, so average nest height across all habitat types is shown on this graph. In all habitat types, the proportion of dead vegetation in the vertical profile was highest immediately above the ground and declined with increasing height. With the exception of the Goodding willow and tamarisk-mesquite habitats, the densest live foliage occurred between 3 and 4 m above the ground and was at or immediately above average nest height. In Goodding willow, the densest foliage occurred above 7 m above the ground, approximately 5 m above average nest height. In tamarisk-mesquite, the densest foliage was below 2 m above the ground; this was the only habitat type where the densest foliage was below average nest height.

Nests in Formerly Occupied Areas

We gathered vegetation data at 44 old nests at Mesquite, Mormon Mesa, Muddy River, and Topock. We were able to locate the exact nest fork in 28 cases and located the nest tree but were unsure of the correct fork in 12 additional cases. In three cases we located the nest vicinity (within 5 m of the nest location) but were unable to verify that we had located the exact nest tree, and in one case the nest tree was clearly no longer there, and we centered the vegetation plot on the nearest adjacent tree.

Vegetation at nest sites differed between occupied and unoccupied periods in more than one variable at each study area; however, the characteristics that differed were not consistent among sites (Tables 5.3 and 5.4). At Mesquite, nest sites had greater canopy closure, more live stems <2.5 cm dbh, fewer dead stems 2.5–8 cm dbh, more live foliage at nest level, and less dead foliage at and below nest level when they were active compared to when the area was abandoned. Vegetation at nest sites at Mesquite also consisted of a larger proportion of native vegetation when the territory was occupied than when it was abandoned. At Mormon Mesa, nest sites had greater canopy closure, more live stems <2.5 cm dbh, more live foliage above the nest, and more dead foliage at nest level when they were occupied versus when territories had been abandoned. At Muddy River, nest sites had more live stems <2.5 cm dbh, less dead foliage at nest level, and a greater percentage of native vegetation when they were occupied, while at Topock Marsh, nests had more live stems 2.5–8 cm dbh and more dead foliage below nest level when they were occupied. When all study areas were combined (Table 5.5), nest sites had greater canopy closure, more live stems <2.5 cm dbh, fewer dead stems 2.5–8 cm dbh, more live foliage at and below nest level, and a greater percentage of native vegetation when they were active versus when the territory was abandoned.

[1] Arrows indicate the direction of change of the variable between occupied and unoccupied periods for each study area (MESQ = Mesquite, MOME = Mormon Mesa,
MUDD = Muddy River, TOPO = Topock Marsh, while color indicates the statistical significance of the change as follows: red is P <0.05, blue is 0.05< P <0.10, black is P >0.10.

DISCUSSION

Currently Occupied Territories

The purpose of vegetation measurements of occupied habitat is to provide quantitative guidelines for restoration efforts. Coyote willow and Goodding willow are the two habitat types that are most likely to be replicated in restoration areas. Mesquite West contains the only extensive stand of coyote willow known to be occupied by territorial willow flycatchers along the lower Colorado River and tributaries in any year since 2003. Occupied coyote willow habitat at Mesquite encompasses approximately 3 ha in the eastern and central portions of Mesquite West and is surrounded by cattail marsh and mixed coyote

willow and tamarisk. Occupied even-age Goodding willow habitat occurred in 2008 on less than 1 ha on the southern end of the Overton WMA site at Muddy River and at Iceberg Canyon in Grand Canyon; however, vegetation data were not collected at Iceberg Canyon. Occupied Goodding willow habitat also occurred in previous years at RM 274.5 and RM 285.3 in Grand Canyon.

Sample sizes for the coyote willow and Goodding willow habitat types in 2008 are small (eight and two, respectively) and likely do not provide an accurate representation of the range and variance in vegetation characteristics in each habitat type. In future reports, data from 2008 will be combined with data collected in future years as well as data collected within active territories between 2003 and 2005 to provide a more comprehensive description of each habitat type.

Although other vegetation types occupied by willow flycatchers are not likely to be created in restoration areas, descriptive data are provided for these habitats to assist in the evaluation of areas to determine their suitability as flycatcher breeding habitat. Data from these other vegetation types may also be useful in illustrating structural similarities between occupied areas in different habitat types. Small sample sizes preclude meaningful comparisons of the 2008 data across habitat types.

Nests in Formerly Occupied Areas

The areas of Mesquite and Mormon Mesa that contained flycatcher nests in previous years but were abandoned in 2008 primarily consisted of areas that were affected by the winter floods of 2004–2005. The eastern edge of Mesquite West experienced flooding and deposition, which appeared to change the flow of water such that the area was no longer inundated. In 2005 we noted that this portion of Mesquite West had reduced foliage density and many of the willows were yellow and dying (Koronkiewicz et al. 2006a). The vegetation did not recover in subsequent years, and this area has not been occupied by flycatchers since 2005. The vegetation at Bunker Farm has also changed noticeably since it was last occupied by breeding flycatchers in 2005. The adjacent agricultural field, which supplied runoff to the site, has been fallow since 2005, and the stands of coyote willow and many of the Goodding willow at Bunker Farm were dead by 2008.

Areas of Mormon Mesa containing most of the old nests were also affected by the 2004–2005 winter floods, which deposited sediment and changed water flow patterns such that nesting areas were no longer inundated. We sampled old nests in Mormon Mesa North and the eastern half of Virgin River #1 North, both of which experienced progressive death of native vegetation since the flood and have not been occupied by flycatchers since 2005. We also sampled one nest from 2006 in the southern end of Virgin River #2; this area was unoccupied in 2007–2008, though no obvious changes in vegetation were noted.

The changes in vegetation that were noted in qualitative site descriptions were also apparent in the vegetation data, with both Mesquite and Mormon Mesa showing less canopy closure, fewer live stems, less live foliage, and more dead foliage in 2008 than when the nests were occupied. Both sites also showed a trend toward decreased canopy height. Nest sites at Mesquite had also lost a significant percentage of their native vegetation, while nest sites at Mormon Mesa showed a trend in this same direction. Canopy closure, canopy height, and the percent native vegetation were all found to be important in differentiating nest sites from non-use areas (McLeod et al. 2008a), and it is likely that decreases in canopy cover and canopy height and the death of native vegetation at Mesquite and Mormon Mesa made portions of those sites unsuitable for nesting flycatchers.

Flycatcher nests at Muddy River have occurred primarily in two areas, one in the northern half of Overton WMA and the other at the southern tip of Overton WMA. The northern portion was occupied each year from 2004 to 2007 but was abandoned in 2008, and the majority of the old nests occurred in this area. We sampled one additional nest at Overton Pond, which was occupied in 2007 but not 2008.

Areas adjacent to the old nests sites at Overton WMA were bulldozed prior to the 2008 breeding season (see Chapter 2), but no obvious habitat changes were noted at the old nest sites themselves. However, vegetation data showed a decrease in live stems <2.5 cm dbh, an increase in dead foliage density at nest height, and a decrease in the percent of native vegetation. There was also a trend toward decreased canopy closure. It is possible that vegetation in the area has changed, although this was not obvious from qualitative descriptions of the site, decreasing the suitability of the area for flycatchers. Bulldozing activities in the vicinity of old nests could also have contributed to abandonment of the area, or the site could have been unoccupied in 2008 as the result of interannual variation in site occupancy. Monitoring of the site in future years will help determine whether abandonment of the site was a temporary or long-term phenomenon.

Old nests at Topock occurred in PC6-1, Pig Hole, and 250M all of which were occupied in 2004 and/or 2005. No obvious changes in vegetation have been noted in any of these sites, though vegetation measurements showed a decrease in the number of live stems 2.5–8 cm dbh and a decrease in dead foliage below the nest. There were also trends toward decreased live foliage below the nest and decreased dead foliage at nest height. A decrease in the number of live stems and decreases in foliage density could reduce suitability of the sites for flycatchers. The number of territories at Topock has varied widely over the years, and the abandonment of certain sites may also reflect a lower overall number of territorial flycatchers. Territorial individuals would be expected to occupy optimal habitats first, and the areas that have not been occupied since 2005 may represent sub-optimal habitat.

The overall habitat changes between occupied and unoccupied periods for all study areas combined, along with an examination of which habitat variables changed in a consistent direction across study areas, lend further insight into which vegetation characteristics seem to be important to flycatcher occupancy. Live foliage density below, at, and above nest height; canopy height; canopy closure; number of live stems <2.5 cm dbh and 2.5–8 cm dbh; and percent native decreased in three or four study areas between occupied and unoccupied periods. Number of dead stems 2.5–8 cm dbh, dead vertical foliage density above nest height, and percent woody ground cover increased in three or four study areas between occupied and unoccupied periods. These trends are all consistent with abandoned areas having experienced a temporal decrease in the density of live vegetation, particularly of native species. McLeod et al. (2008a) reported similar differences between occupied and unoccupied areas when habitat patches were sampled to identify spatial habitat variation that affected flycatcher occupancy. Flycatchers typically occupied areas that had greater canopy height, canopy closure, foliage density, stem density, and percent native vegetation than unoccupied areas.

Chapter 6

MICROCLIMATE

INTRODUCTION

Our objective for microclimate sampling is to provide a quantitative summary of microclimate conditions within occupied territories in various vegetation types. These descriptive summaries will provide guidance for managers working to restore and create riparian habitat to meet the obligations of the LCR MSCP and will provide a means to evaluate habitats to determine if the microclimate resembles that in occupied flycatcher territories. The Pahranagat study area was excluded from the characterization of occupied territories because the study area is approximately 650 m higher in elevation and experiences a cooler climate than the LCR MSCP study area.

In addition, we investigated whether changes in microclimate characteristics might have contributed to the abandonment of some areas by flycatchers. We identified several areas that had been occupied by nesting flycatchers in at least one previous year from 2003 to 2007 but were unoccupied in 2008, and we relocated old nest sites at which we had collected microclimate information in the year the nest was active. We resampled the microclimate at these nests to see whether microclimate characteristics had changed. Comparison of microclimate data collected when a nest site was active versus when the area was abandoned may elucidate how changes in microclimate through time may influence flycatcher occupancy. These results will provide additional quantitative information on the characteristics of microclimate within flycatcher nesting territories.

METHODS

Currently Occupied Territories

We collected microclimate measurements at one location for each territorial male flycatcher we identified, regardless of the length of time the male was resident and whether or not he obtained a mate.

Temperature and Relative Humidity (T/RH) Measurements

Measurements of temperature and relative humidity (T/RH) were recorded automatically every 15 minutes using a HOBO H8 Pro (Onset Computer Corporation, Pocasset, MA) that combines a thermometer (degrees Celsius), relative humidity monitor, and digital data logger. We camouflaged all HOBO units by placing them in an inverted small, plastic container coated with spray adhesive and local vegetation. The opening at the bottom was covered with shadecloth, allowing free air circulation around the unit. One HOBO unit was placed within each active flycatcher territory. We estimated the center of the male's territory (see Chapter 5) and then determined the location of the HOBO unit by means of the following instructions and the use of random number sequences:

(1) The compass direction to walk from the territory center, given in degrees from north, was determined from a random number sequence.

(2) The distance (between 0 and 20 m) to walk in the designated direction was determined from a random number sequence. Once that distance was traveled, the closest woody tree or shrub was selected for data logger placement.

(3) The HOBO unit was placed at a randomly selected height within the range of flycatcher nest heights documented at that study area in 2003–2007 (McLeod et al. 2008a). The distribution of random numbers followed the distribution of nest heights. If the chosen tree or shrub was of insufficient height to accept the height from the random number sequence, then field personnel placed the HOBO unit at the first height in the sequence that was less than the height of the tree or shrub. If no nests had been previously recorded at that study area, field personnel used the height sequences from the nearest study area with known nests.

(4) The distance (0–2 m) at which the HOBO was placed from the bole of the tree or center of the shrub was determined from a random number sequence. If the tree or shrub was of insufficient radius to accept the distance from the random number sequence, then field personnel placed the unit at the first number in the sequence that was less than the radius of the tree or shrub.

(5) The compass direction, given in degrees from north, at which the unit was placed from the bole of the tree or center of the shrub was determined from a random number sequence. If there was no branch in this compass direction that would support the data logger at the height and distance specified in (3) and (4), field personnel proceeded clockwise around the tree or shrub until a suitable branch was located.

If, as presented in (3) and (4), a number from a subsequent random number sequence (sequence meaning a row in the random number table) was used because the number in the initial sequence was too high, then both sequences were considered used and no longer available for future use. If these directions took field personnel outside of the riparian zone or to a site without trees or shrubs, they returned to the territory center and used the next sequence of random numbers.

HOBO data loggers were deployed as soon as the male was confirmed as being resident and were left in place throughout the breeding season. The logger was downloaded when vegetation measurements were collected at the end of the breeding season, and the logger was left in place to collect data until the start of the 2009 breeding season.

Soil Moisture (SM) Measurements

A ThetaProbe ML2x coupled to an HH2 Moisture Meter Readout (Macaulay Land Use Research Institute, Aberdeen, UK, and Delta-T Devices, Cambridge, UK, respectively) was used to gather soil moisture (SM) data. The SM readings (nine per site) were recorded directly beneath the HOBO logger (plot center) and at 1.0 and 2.0 m from plot center in each cardinal direction. Soil moisture readings were collected when the HOBO logger was deployed and at two-week intervals throughout the breeding season until the HOBO logger was downloaded. Soil moisture was recorded both as voltage (mV) and as volumetric water content (%).[1] Soil type on the HH2 was set to mineral soil. For any SM measurement point that was underwater, we recorded the depth of standing water and assigned a value of 994 mV, which is equivalent to 50% volumetric water content, or fully saturated soil. All mV values greater than 994 were also reassigned as 994 mV, because this reading represents fully saturated soil and because the mV to percent relationship becomes excessively nonlinear for mV readings above this point. Each time we collected soil moisture data, we also recorded the distance to the nearest standing water or saturated soil and recorded the approximate percentage, as estimated in the field, of the site within 20 and 50 m of the data logger that contained inundated or saturated soil.

[1] The soil moisture logger measures the dielectric constant of moist soil via a direct current voltage, which is converted to volumetric soil moisture with conversion tables. For very high (above ~1000 mV) or low (below ~90 mV) voltage readings, the HH2 reports volumetric soil moisture as "above" or "below" the table, respectively. To eliminate these qualitative readings, we recorded both mV and volumetric soil moisture.

A soil sample was collected from beneath each HOBO data logger. Samples were approximately the size of a medium apple, collected from the surface down to and including a depth of 5 cm, and placed in a heavy zip-lock plastic bag labeled with the site designation. These samples will contribute to an ongoing analysis of soil texture, which strongly influences capillary action and therefore overall SM (Sumner 2000).

Statistical Analyses

Soil moisture data were entered into a database as they were collected during the field season. We downloaded data from the HOBO data loggers into databases at the end of the field season. We merged all data to create one dataset for further analysis. We summarized the following variables for each HOBO location:

- Mean soil moisture from plot center to 2.0 m from plot center
- Distance to nearest standing water or saturated soil
- % of the site within 20 m that was inundated or saturated
- % of the site within 50 m that was inundated or saturated
- Maximum diurnal temperature
- Minimum nocturnal temperature
- Daily temperature range (diurnal maximum minus nocturnal minimum)
- Mean diurnal vapor pressure[2]
- Mean nocturnal vapor pressure

Soil moisture variables were summarized per visit, and temperature/humidity variables were summarized on a daily basis. We determined diurnal and nocturnal periods by using the actual daily sunrise and sunset times reported for the region by the National Weather Service (2008). We selected the above measures of temperature and humidity for analysis because they were the most highly correlated with other variables or were the most useful in distinguishing use areas from non-use locations (McLeod et al. 2008a). Territories were grouped according to vegetation type (see Chapter 5), and microclimate variables were averaged for each vegetation type over the following two-week periods to show how microclimate conditions changed throughout the breeding season: 12–31 May, 1–15 June, 15–30 June, 1–15 July, 16–31 July, and 1–15 August.

Analyses were conducted using SAS® v.9.1.3 (SAS Institute 2003) and Stata® v.9.2 (StataCorp 2006). Data are presented as mean (standard error) unless otherwise noted.

Nests in Formerly Occupied Areas

We used the UTM coordinates of the nest, nest tree species, nest height, and nest flags that remained in the field to locate old nests. We hung a HOBO logger at the old nest location in May, and the logger remained in place until the end of the breeding season. Soil moisture measurements were taken at two-week intervals as described above.

[2] Vapor pressure, unlike relative humidity, is not influenced by ambient temperature, and may be a more biologically meaningful measure of water content of the air (e.g., the relative vapor pressure inside and outside an egg determines whether the egg loses moisture). We calculated vapor pressure from the absolute humidity and temperature recorded by the HOBOs.

Statistical Analyses

During the year when each nest was active, microclimate data were collected for a two-week period immediately following the nest being vacated. We selected data from the same two-week period for each nest in 2008. We summarized the following variables for each HOBO location:

- Mean soil moisture from plot center to 2.0 m from plot center
- Maximum diurnal temperature
- Minimum nocturnal temperature
- Daily temperature range (diurnal maximum minus nocturnal minimum)
- Mean diurnal vapor pressure[3]
- Mean nocturnal vapor pressure

We used paired t-tests to compare measures of microclimate at old nests to the measurements collected during the year the nest was active. P-values were similar to those obtained when a non-parametric test (Wilcoxon signed rank sum) was used to compare matched sites. Analyses were conducted using SAS® v.9.1.3 (SAS Institute 2003) and Stata® v.9.2 (StataCorp 2006). Missing data were excluded test-wise. Data are presented as mean (standard error) unless otherwise noted.

To address whether any observed changes in microclimate between occupied and unoccupied periods could be the result of overall changes in regional climate, we obtained weather station data from the National Climate Data Center (www.ncdc.noaa.gov/oa/ncdc.html) for Overton, Nevada (Station ID #265846) and Needles, California (Station ID #723805) for 2003–2008. Maximum and minimum daily temperature data were available for both weather stations, and dew point data were available for Needles. We used one-way ANOVA to test whether temperature and dew point variables differed between years for the June–August period. We used SPSS® Version 16.0 (SPSS Inc.) software for statistical analyses.

RESULTS

Currently Occupied Territories

We deployed HOBO data loggers and collected soil moisture data at 41 active territories. HOBO loggers failed to collect data at three locations, and soil moisture data could not be collected at one location because thick piles of arrowweed and bulrush prevented access to the soil. Microclimate variables are summarized by two-week periods for each vegetation type in Tables 6.1–6.8. These same variables are plotted in Figures 6.1–6.9 to facilitate comparisons between vegetation types.

All vegetation types exhibited moist soil conditions throughout the breeding season. Goodding willow had the wettest conditions, with fully saturated soil throughout the season and a minimum of 60% of the surrounding area within 50 m having surface water at each visit through the end of July. Soil conditions showed a general drying trend, with the inundated percentage of the surrounding area declining through the season, in Goodding willow with tamarisk understory, tamarisk with scattered Goodding willow at Mormon Mesa, and tamarisk with scattered Goodding willow at Topock.

[3] Vapor pressure, unlike relative humidity, is not influenced by ambient temperature, and may be a more biologically meaningful measure of water content of the air (e.g., the relative vapor pressure inside and outside an egg determines whether the egg loses moisture). We calculated vapor pressure from the absolute humidity and temperature recorded by the HOBOs.

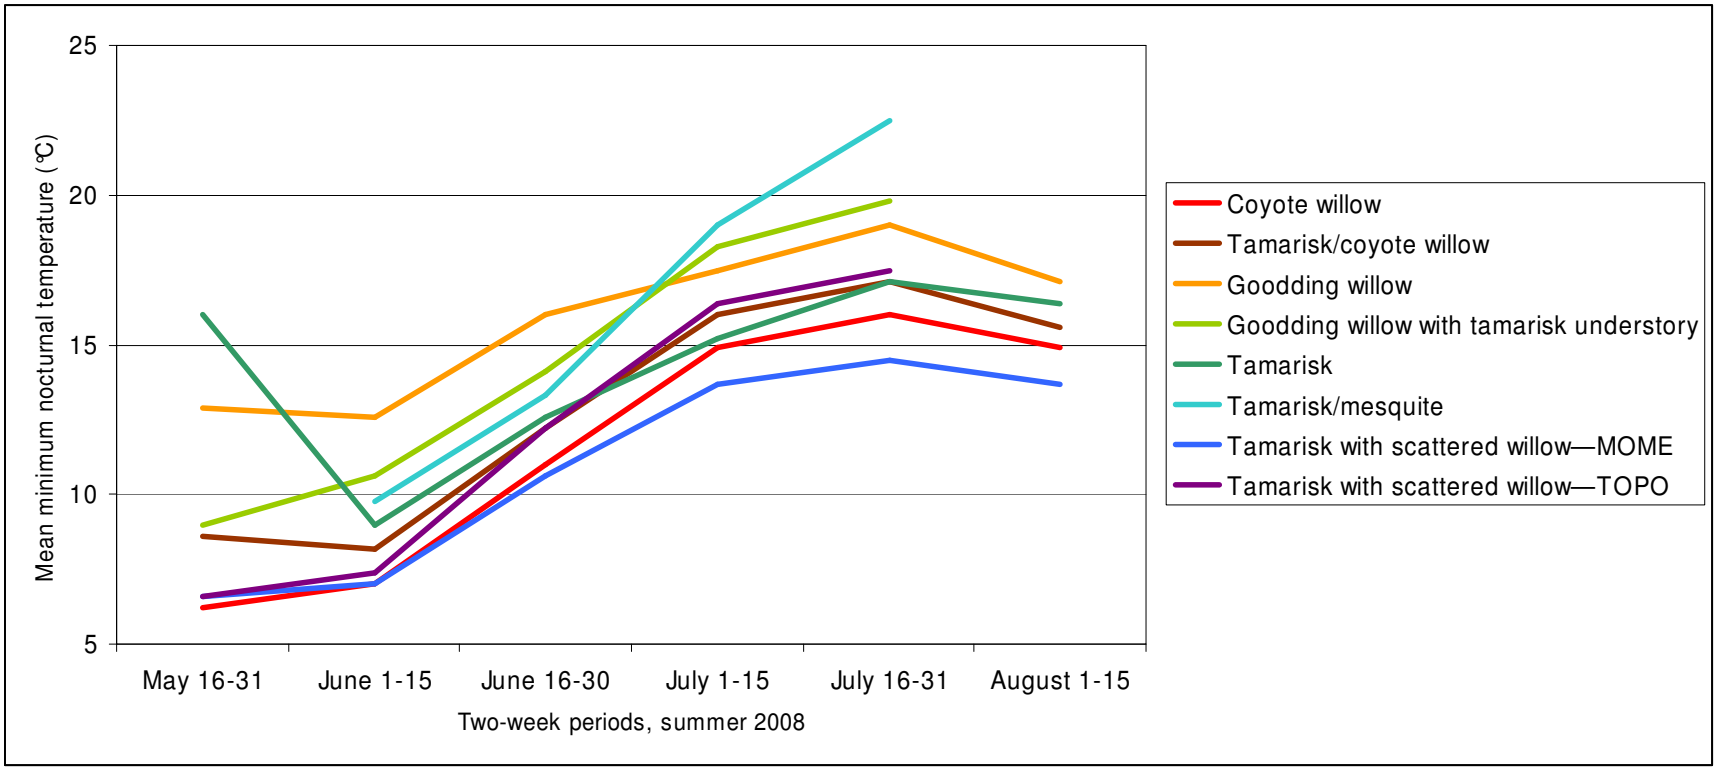

Figure 6.6. Mean minimum diurnal temperature at Southwestern Willow Flycatcher territories in various vegetation types, Lower Colorado River and tributaries, 2008.

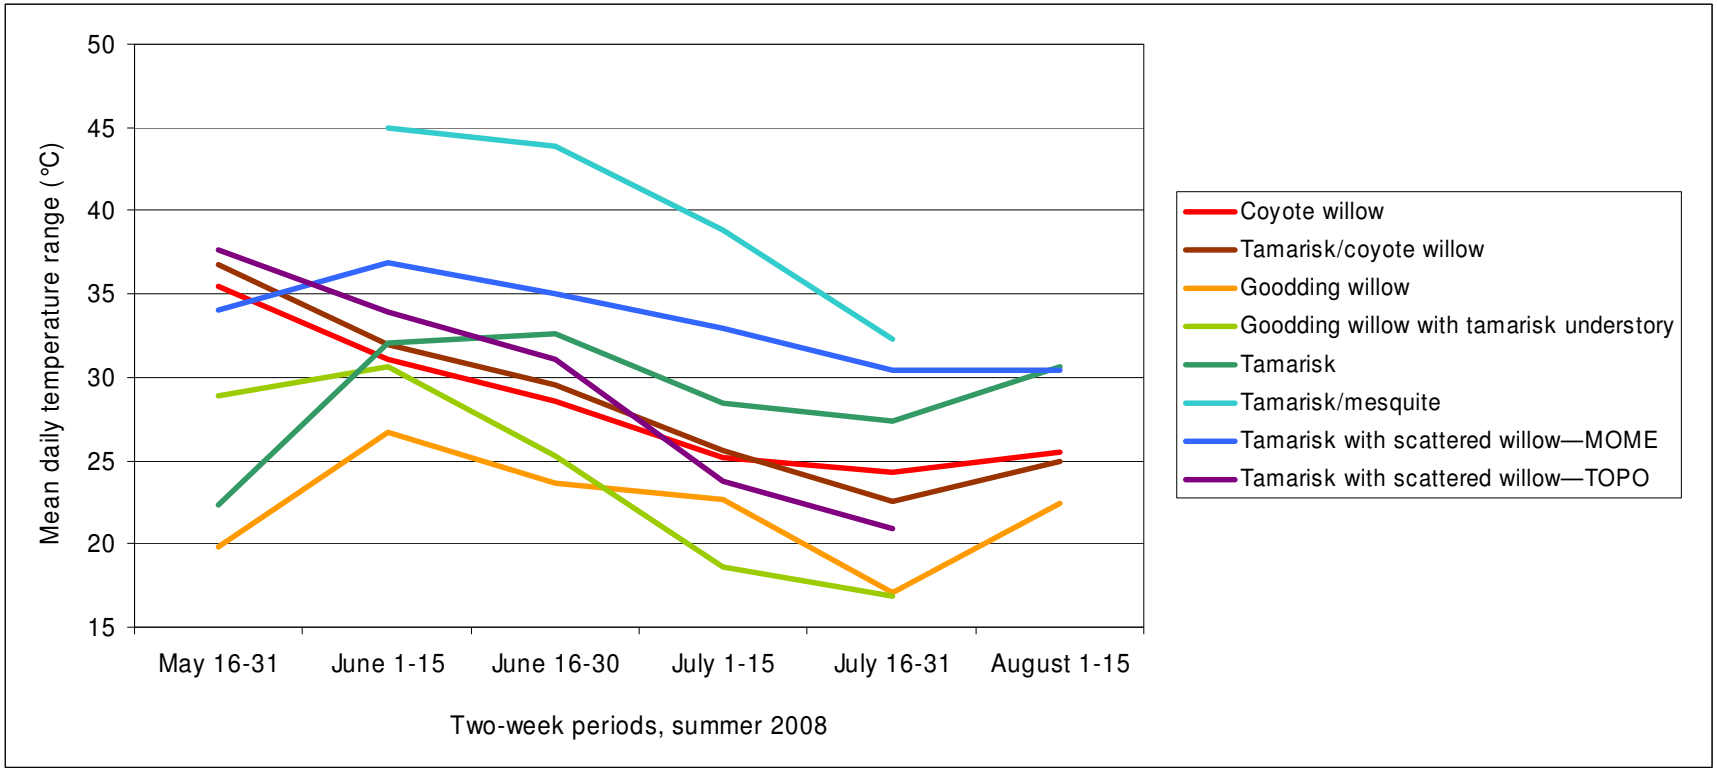

Figure 6.7. Mean daily temperature range at Southwestern Willow Flycatcher territories in various vegetation types, Lower Colorado River and tributaries, 2008.

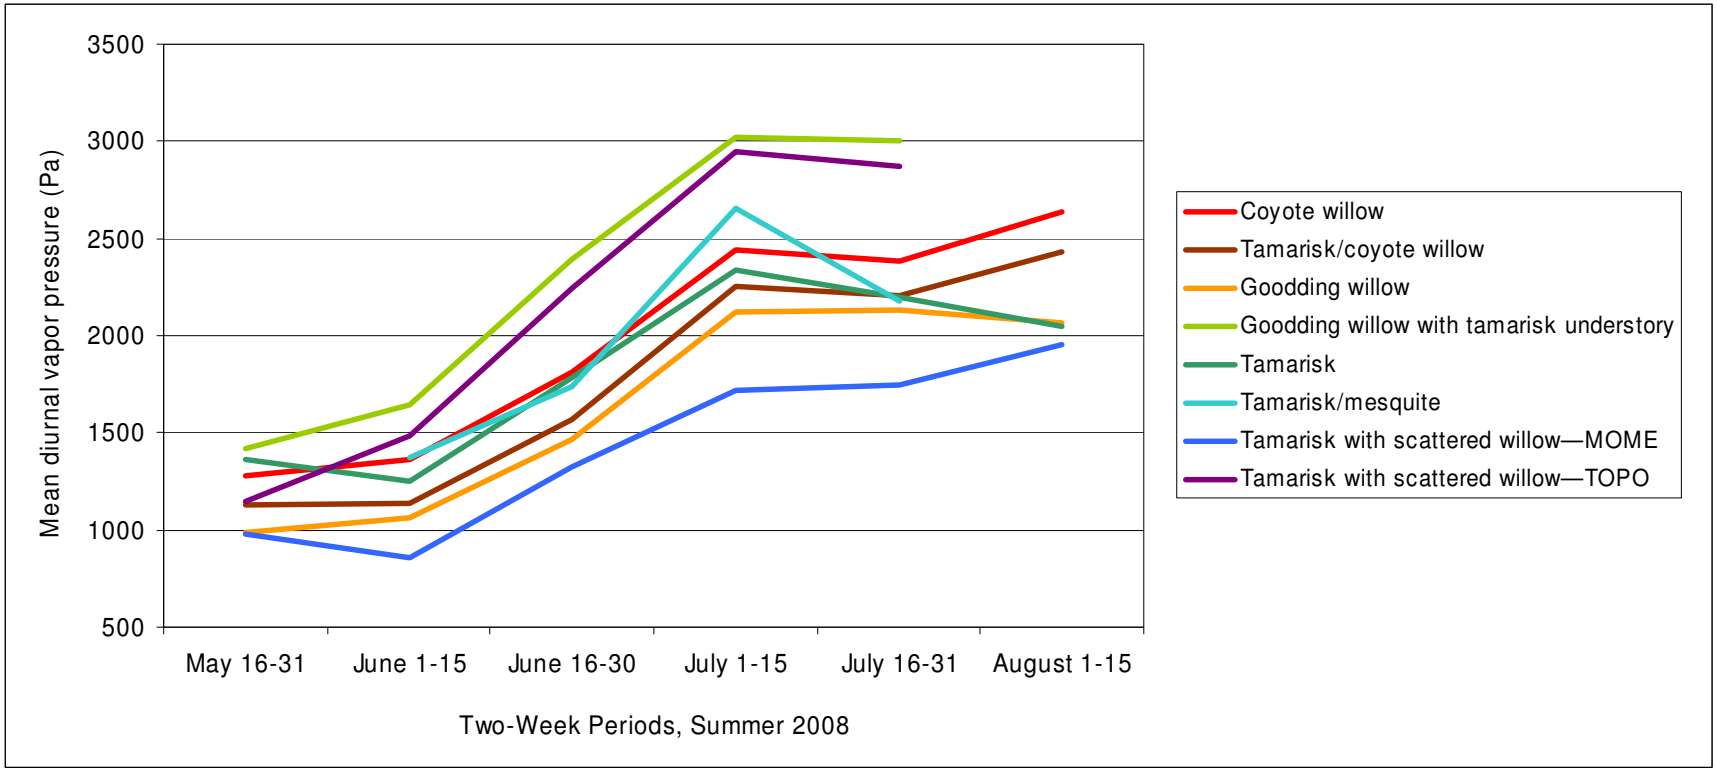

Figure 6.8. Mean diurnal vapor pressure at Southwestern Willow Flycatcher territories in various vegetation types, Lower Colorado River and tributaries, 2008.

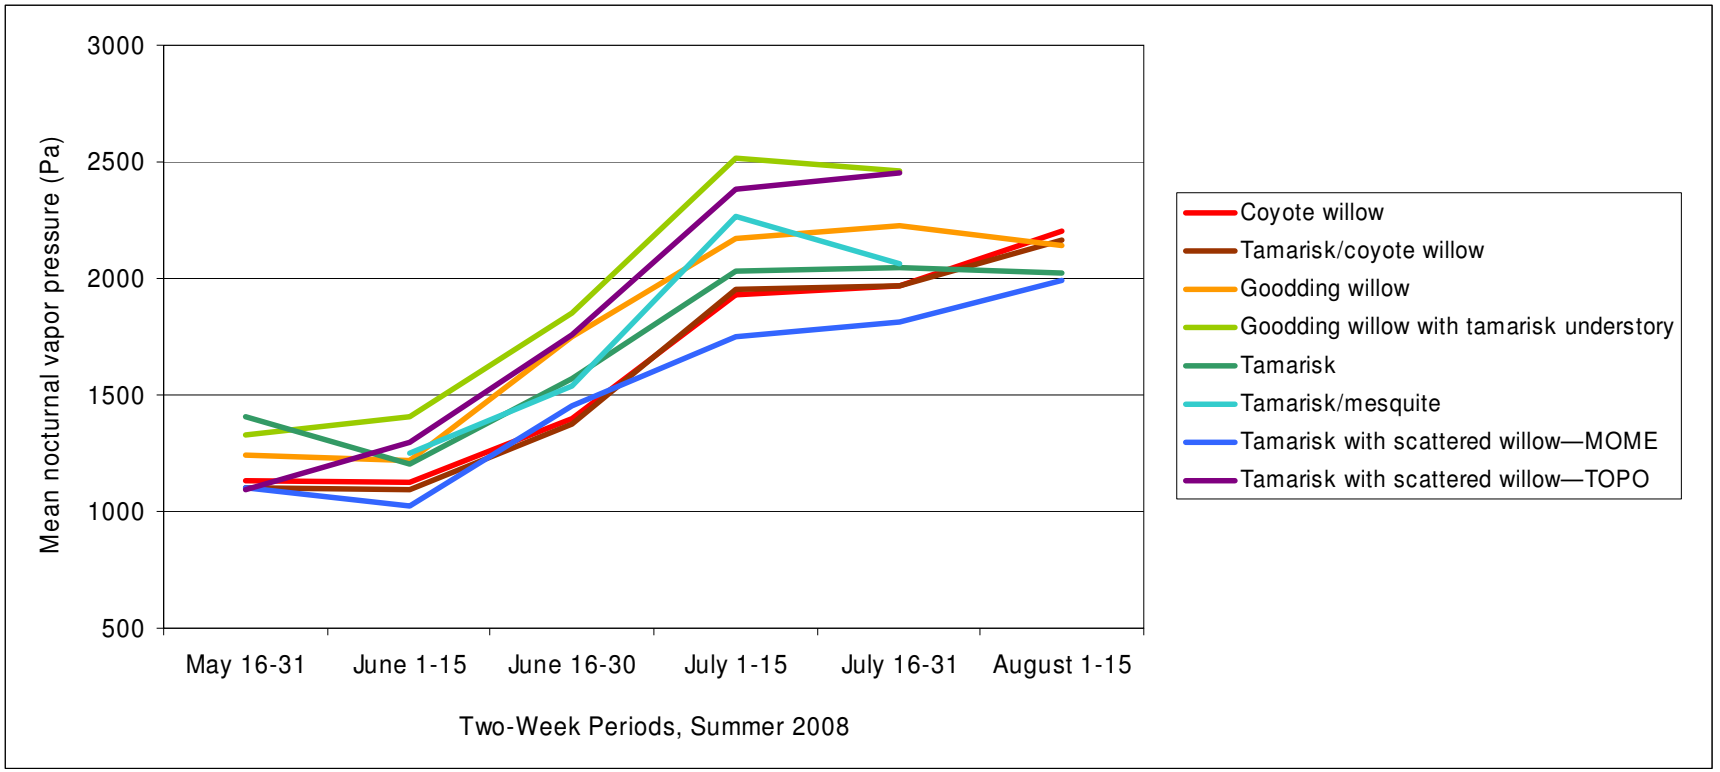

Figure 6.9. Mean nocturnal vapor pressure at Southwestern Willow Flycatcher territories in various vegetation types, Lower Colorado River and tributaries, 2008.

Daily maximum temperatures spanned a range of approximately 15°C among habitat types. Daily minimum temperatures showed a much smaller range, spanning only 5°C. Habitat types with high daily maximum temperatures also tended to have low daily minimum temperatures and thus had the largest temperature ranges. Tamarisk/mesquite and tamarisk with scattered Goodding willow at Mormon Mesa showed the highest daily temperature ranges, while Goodding willow and Goodding willow with tamarisk understory had the most moderate temperature ranges.

Vapor pressure increased throughout the season for all habitat types. Vapor pressure was highest in Goodding willow with tamarisk understory and in tamarisk with emergent Goodding willow at Topock. Vapor pressure was lowest in tamarisk with emergent Goodding willow at Mormon Mesa.

Nests in Formerly Occupied Areas

We located 44 old nests at Mesquite, Mormon Mesa, Muddy River, and Topock Marsh. We were able to locate the exact nest fork in 28 cases and located the nest tree but were unsure of the correct fork in 12 additional cases. In three cases we located the nest vicinity (within 5 m of the nest location) but were unable to verify that we had located the exact nest tree, and in one case the nest tree was clearly no longer there, and we placed the data logger on the nearest adjacent tree. Five of the 44 HOBO data loggers failed to collect data, while two data loggers collected temperature but no humidity data. Soil moisture data from the occupied period were unavailable for the three nests that were active in 2003.

Microclimate at old nests sites differed between occupied and unoccupied periods in at least one variable at both Mesquite (Table 6.9) and Mormon Mesa (Table 6.10). At Mesquite, nest sites had higher soil moisture when they were occupied versus when they were abandoned, while at Mormon Mesa nest sites had wetter soils in 2008 versus when the nest was occupied. Mean maximum diurnal temperature and mean daily temperature range were greater during the unoccupied period at Mormon Mesa. No statistically significant differences in microclimate variables were detected at Muddy River (Table 6.11) or Topock (Table 6.12) between occupied and unoccupied periods, but general trends were evident when data from all sites were examined together (Table 6.13). At three of the four study areas, nest sites had higher measures of all three temperature variables and lower measures of both humidity variables when the sites were unoccupied versus when they were occupied. Topock was the study area that generally countered these trends, with lower temperatures and higher humidity during the unoccupied period. When all sites were considered together, mean maximum diurnal temperature was significantly higher during the unoccupied period. Soil moisture, daily temperature range, and diurnal humidity all showed trends (P-values <0.1), with nest sites having more extreme temperatures and lower soil moisture and humidity during the unoccupied period.

Mean daily maximum and minimum temperature recorded at the Overton weather station did not differ between 2008 and any of the preceding five years for the June–August period. At the Needles weather station, mean maximum daily temperature was higher ($F_{5,537} = 7.6$, $P < 0.001$) in June–August 2008 (109.3 °F) than during the same period in 2004 (106.9 °F), while mean minimum daily temperature in 2008 (83.2 °F) was lower than in 2006 (86.2 °F) and higher than in 2004 (81.4 °F; $F_{5,537} = 7.8$, $P < 0.001$). Average dew point at Needles was lower ($F_{5,537} = 11.4$, $P < 0.001$) in 2008 (42.6 °F) than in 2003 (55.3 °F) or 2004 (48.6 °F).

DISCUSSION

Currently Occupied Territories

The hydrological conditions recorded in occupied territories in 2008 showed that flycatcher territories contained damp or wet soils, with the distance to surface water generally being less than 30 m, and in most cases between 10 and 50% of the surrounding area within 50 m containing saturated or inundated soils during each visit to the site. The soil moisture conditions observed in occupied territories generally mirrored those observed at the same sites in previous years.

Tamarisk with scattered Goodding willow at Topock Marsh had the wettest conditions in May and became progressively drier through the rest of the season. Soils within the Goodding willow with tamarisk understory vegetation type also showed a general drying trend through the season, with distance to water increasing and the percentage of inundated soils decreasing. Tamarisk with scattered Goodding willow at Mormon Mesa was the only vegetation type that was influenced by an undammed river, and soil moisture conditions showed a steady drying trend until the arrival of monsoon storms in late July. In early July, prior to monsoon storms, the river went subsurface in much of the Mormon Mesa study area and there was virtually no surface water within 50 m of the active territories. After the arrival of monsoons, surface flow was restored in the river and the inundated percentage around the territories increased, though both soil moisture and inundated percentages were markedly lower than in May and June.

Coyote willow and tamarisk with coyote willow showed fluctuating soil moisture levels throughout the flycatcher breeding season, with soil moisture levels being the highest in early June and lowest in the second half of July. These habitat types are influenced by irrigation runoff, and in previous years we observed highly variable water levels within the site, with fluctuations sometimes occurring on a daily basis.

Goodding willow habitat at Overton WMA was wetter than in some previous years because of recent beaver activity that resulted in the flooding of most of the site.

Temperature and humidity varied across habitat types but followed the same patterns we had observed in some of the habitat types in previous years, with tamarisk with emergent willow at Mormon Mesa being hot and dry relative to other habitat types, and tamarisk with emergent willow at Topock being relatively humid. In general, habitats with a significant native component tended to be cooler and more thermally moderate than those dominated by tamarisk.

Nests in Formerly Occupied Territories

Willow flycatchers along the lower Colorado River and tributaries selected nest sites that were cooler, wetter, and more thermally moderate than unused sites in the adjacent landscape (McLeod et al. 2008a), and we anticipated seeing similar differences when we examined temporal, rather than spatial, variation in habitat use. We observed changes in microclimate in the direction we anticipated at Mesquite, with abandoned nest sites having drier soils and a trend toward higher maximum daily temperatures than they had when they were occupied. The change in soil moisture was likely caused by flood deposition, which altered water flow patterns in the area. These hydrological changes contributed to changes in the vegetation (see Chapter 5), with nest sites having taller canopy height, greater canopy closure, and a higher percentage of native vegetation when they were occupied. Changes in both hydrology and vegetation likely influenced microclimate; canopy height, canopy closure, and percent native vegetation are all inversely related to maximum daily temperature (McLeod et al. 2008a). There were no differences

in average maximum or minimum temperature between 2008 and any of the five preceding years as recorded at the weather station in Overton; therefore, temporal differences observed at old nests in the Virgin and Muddy River area are unlikely to be the result of overall changes in regional climate.

We observed similar vegetation and temperature changes at Mormon Mesa, with abandoned nest sites having less canopy closure and more extreme temperatures than when they were occupied. We did not observe the same shift in soil moisture conditions, however, with abandoned nest sites actually having higher soil moisture than when they were occupied. Soil moisture in 2008 was likely influenced by a rain storm immediately prior to collecting soil moisture readings in late July. Soil moisture at the nests at Mormon Mesa when they were occupied was lower than in any of the other study areas. It is possible that these areas at Mormon Mesa were already dry and in decline when they were occupied in 2003 and 2004.

We did not observe any statistically significant changes in microclimate at old nests at Muddy River, although the direction of change of all variables was consistent with what we observed at Mesquite. As discussed in Chapter 5, occupancy at Muddy River may have been influenced by bulldozing activity in the vicinity, rather than by changes at the nest sites themselves.

Temporal changes in microclimate at Topock were opposite those we would have expected, with old nest sites having a smaller temperature range when unoccupied. The direction of change in soil moisture and humidity was also counter to what would be anticipated, with nest sites having higher soil moisture and higher humidity when unoccupied. These changes are also counter to what was observed at the Needles weather station, which had higher maximum temperature and lower dew point in 2008 than in 2004; thus, regional climate is unlikely to have influenced the changes we observed at the old nests. The data from Topock show no evidence that nest sites were abandoned because of changes in moisture or temperature that led to less suitable microclimate conditions. As discussed in Chapter 5, changes in occupancy patterns at Topock may be related to varying numbers of territorial individuals rather than to temporal changes in habitat suitability.

Chapter 7

HABITAT MONITORING: PARKER TO IMPERIAL DAMS

INTRODUCTION

Southwestern Willow Flycatcher nests and breeding territories are typically located near rivers, streams, and open water (Sogge and Marshall 2000) or over wet soil (Flett and Sanders 1987, Harris et al. 1987, Harris 1991). Nest substrate plants are often rooted in or overhang standing water. Although the association between breeding flycatchers and open water or wet soil is widely recognized by managers and scientists alike, the exact nature of the association is poorly quantified. Water may be a direct environmental cue for flycatcher nesting behavior or it may be the ultimate cause of proximate factors such as vegetation composition and structure, prey base, and microclimate.

Anthropogenic or natural modifications to surface water resources (i.e., fluvial hydrology and geomorphology) can modify existing and potential flycatcher breeding habitat and therefore have the potential to modify flycatcher abundance, distribution, and nesting success (Graf et al. 2002). For example, nine flycatcher territories at San Marcial on the middle Rio Grande in New Mexico exhibited a near absence of nesting attempts in 1996 when a combination of drought, upstream dam operations, and upstream withdrawals for irrigation removed all surface water (Johnson et al. 1999). This was in contrast to previous (1994, 1995) and subsequent (1997) years when active nests were documented at the site, with the river flowing in those years. A nearby control site that contained water exhibited multiple nesting attempts during all four years, leading Johnson et al. (1999) to suggest that the presence of water was a fundamental requirement for nesting. A similar pattern was observed along the Gila River in Arizona when decreased streamflow from 2002 to 2004 coincided with the number of flycatcher territories declining by nearly half each year (Munzer et al. 2005). Since 2004, flows within the Gila River have been greater and more consistent, and correspond with a continuing increase in flycatcher territories (14 to 62) from 2004 to 2008 (Graber and Koronkiewicz 2008). The high degree to which willow flycatchers are associated with standing water can also be seen by correlating flycatcher habitat occupancy and breeding patterns with the presence/absence of standing water in areas like Bill Williams, with flycatchers breeding only in years when sites contained standing water (this document Chapter 2).

Flow characteristics of the lower Colorado River have been modified by numerous dams and irrigation withdrawals (Rosenberg et al. 1991). The river reach between Parker Dam and Imperial Dam is regulated by releases from Parker Dam, which has been in operation since 1939. Existing riparian habitat in the Parker to Imperial reach has likely adjusted to historical water release patterns from Parker Dam and appears to be in a stable or declining condition (Lower Colorado River Multi-Species Conservation Program 2004). Implementation of the Secretarial Implementation Agreements/California 4.4 Plan (hereafter SIAs) by Reclamation would change the point of diversion for up to 400,000 acre-feet of California apportionment water for up to 75 years (USFWS 2001). The point of diversion, previously located below Parker Dam at Imperial Dam, would change to a point above Parker Dam, resulting in lower water levels in the river between Parker and Imperial. The change in point of diversion was scheduled to begin in 2002.

River flow changes related to the change in point of diversion have the potential to further modify riparian habitats below Parker Dam, habitats that are presently considered potentially suitable for willow flycatcher (USFWS 2001:47). Reclamation (2000) estimated that implementation of the SIAs will cause a drop in floodplain groundwater levels of 1.55 feet (0.47 m) or less. As a result, 372 acres (151 ha) of

occupied[1] Southwestern Willow Flycatcher habitat could lose their moist soils. This loss could influence plant species composition (loss of cottonwood and willow) and structure (loss of vegetation volume) over an undetermined length of time. In addition, Reclamation estimated that 5,404 acres (2,187 ha) of potential flycatcher habitat could be influenced by the drop in groundwater level. These changes may affect the distribution, abundance, occupancy, and prey base of Southwestern Willow Flycatchers in the Parker to Imperial reach.

In 2004, Reclamation completed a pilot year of habitat monitoring by deploying temperature/ humidity data loggers at several sites in the Parker to Imperial reach. Reclamation then initiated a more comprehensive, long-term study in 2005 for the purpose of addressing how the above hydrological changes might affect riparian habitats along the Parker to Imperial reach. The objective is to monitor 372 acres (151 ha) of occupied Southwestern Willow Flycatcher habitat between Parker and Imperial Dams for 10–15 years to determine how microclimate, vegetation, and groundwater conditions might be affected by the SIAs water transfer actions. Monitoring did not commence until after diversions started; therefore, antecedent conditions are unknown and monitoring analyses focus on detecting change through time rather than comparing current conditions to a baseline. An additional objective was to compare microclimate characteristics of sites in the Parker to Imperial reach with those at flycatcher breeding areas. This chapter reports the results of this study to date.

METHODS

In 2005, we selected a subset of sites that are currently surveyed for the presence of willow flycatchers for inclusion in the habitat monitoring study. We chose 11 sites distributed along the Parker to Imperial reach that are reasonably accessible, and where we believed groundwater levels were influenced primarily by river levels and not by outside sources such as irrigation return flows. Chosen sites equated to at least 75.3 ha (186 acres) on the California side of the lower Colorado River and at least 75.3 ha (186 acres) on the Arizona side. We also chose four control sites, two above Parker Dam and two below Imperial Dam, to distinguish any changes in microclimate, groundwater, or vegetation caused by water transfer actions from those caused by fluctuations in climate or rainfall. We monitored these same 15 sites from 2005 to 2008. In August of 2006, we initiated habitat monitoring within a consistently occupied breeding site at Topock Marsh to obtain groundwater levels and patterns with which we can compare results obtained at the habitat monitoring sites.

Temperature/Humidity (T/RH) Loggers

In 2005, we deployed HOBO H8 Pro (Onset Computer Corporation, Pocasset, MA) temperature/humidity data loggers at several locations within each site selected for habitat monitoring. All loggers collected data at 15-minute intervals and were placed in inverted plastic containers and camouflaged as described in Chapter 6. All 60 logger locations selected in 2005 were retained in 2006. Two additional data loggers were installed in the Topock Marsh monitoring site in August 2006. A portion of Gila Confluence North, one of the control sites below Imperial Dam, burned in December 2006. As a result of the fire, all vegetation at one HOBO location at the site was killed, and vegetation at another HOBO location was dramatically reduced. These two HOBOs were replaced in May 2007 with HOBOs at new locations within unburned portions of the site.

[1] As per the USFWS, occupied Southwestern Willow Flycatcher habitat is defined as patches of vegetation that are similar to and contiguous with areas where willow flycatchers were detected after 15 June in any year since surveys began in 1996.

Soil Moisture (SM) Measurements

Soil moisture beneath each HOBO logger was measured and recorded using a hand-held ThetaProbe ML2x coupled to an HH2 Moisture Meter Readout (Macaulay Land Use Research Institute, Aberdeen, UK, and Delta-T Devices, Cambridge, UK, respectively). Soil moisture measurements were collected during each presence/absence survey between 15 May and 25 July and when HOBO data were downloaded. Soil moisture measurements, percent of the area containing inundated or saturated soil, and distance to water were recorded as described in Chapter 6.

Vegetation Measurements

We completed vegetation measurements, following the methods described in Chapter 5, at each HOBO location after flycatcher surveys were completed in late July. All HOBO loggers were also downloaded at this time. Vegetation measurements were completed at the same locations as in 2005–2007, with the exception of Gila Confluence North, where vegetation measurements were collected at the two new HOBO locations established in 2007.

Groundwater Measurements

A small-diameter shallow well, or piezometer, was installed in May–August 2005 near each of the 15 sites selected for habitat monitoring to monitor groundwater levels. These 15 piezometers are described in Koronkiewicz et al. (2006a) and were initially downloaded in August–September 2005. One additional piezometer was installed at Topock Marsh in 2006. The piezometer at the Gila Confluence North monitoring site was moved to a new location in July 2007 because the original station was damaged in the brush fire referred to above. In March 2008, a new piezometer was installed at the Cibola Lake monitoring site to replace the original station, which was bulldozed sometime during the summer of 2007.

Piezometer Installation

Installation of the Cibola Lake replacement piezometer employed the same installation process as described in previous reports. The specific model of pressure transducer installed in the original 16 piezometers (In-Situ MiniTroll 500) is no longer manufactured. The Cibola Lake piezometer now makes use of the newest generation of pressure transducer (In-Situ LevelTroll 500), as will any replacement equipment in the future.

Data Collection

A pressure transducer/data logger (15 mini-Troll Standard-P, 5psi and one level-troll 500, 5psi, manufactured by In-Situ Corporation) collected data at each piezometer. These devices measure and record pressure of the water column present in the well, and these pressure measurements are then converted into water levels (in distance below top of casing). Vented cables with data-transfer ports were also used for each data logger. With these cables there is no need to correct measurements for atmospheric pressure changes, and the data can be downloaded at the wellhead without disturbing the pressure transducer in the well.

During the initial installation of the pressure transducers, as well as at each data download thereafter, water levels were manually measured in the piezometers using an electric water level sounder (Solinst-brand). These known water levels were then used to program the pressure transducer with a baseline

measurement from which all other automatically recorded water levels were calculated. The pressure transducers recorded water levels in the piezometers every hour.

Because the pressure transducer is almost the same diameter as the inside of the piezometer, inserting the pressure transducers tends to change the water levels in the piezometer temporarily but drastically. This disturbance persists until the water levels in the piezometer come back into equilibrium with water levels in the aquifer. In areas where there are tight, clayey soils, there can be a slight discrepancy between the pressure transducer measurement of water levels and actual water levels. This discrepancy can be adjusted with a simple correction.

We obtained additional hydrologic data from the U.S. Geological Survey (USGS) regarding streamflow and stage height in the Colorado River at several gages: Colorado River below Parker Dam (09427520) and Colorado River below Imperial Dam (09429500). Lake water levels were also obtained from the USGS for Lake Havasu. In addition, daily water releases were obtained from the Bureau of Reclamation for Parker Dam.[2] Our goal was to define the relationship between the water levels in the piezometers and operation of the reservoirs on the Colorado River.

Statistical Analyses

Microclimate

The following values were calculated for all 15 habitat monitoring sites:

- Mean soil moisture from plot center to 2.0 m from plot center
- Mean distance to saturated/inundated soil
- Mean diurnal temperature
- Mean number of 15-minute intervals above 41°C each day
- Mean nocturnal temperature
- Mean daily temperature range (diurnal maximum minus nocturnal minimum)
- Mean diurnal relative humidity
- Mean diurnal vapor pressure
- Mean nocturnal relative humidity
- Mean nocturnal vapor pressure

The diurnal and nocturnal periods were determined from the daily sunrise and sunset times reported for the region by the National Weather Service (2008).

These values were then calculated for all sites combined and compared to the same values for territory locations at Topock Marsh combined with two sensors placed near the piezometer at Topock Marsh, which was within 50 m of a territory center. These analyses were restricted to 6 May–31 July 2008, the dates during which microclimate data were collected both within territories at Topock and at habitat monitoring locations. One-way ANOVA tests were used to test the difference in means for the T/RH and SM values.

[2] Because hydrologic data are generally collected and presented in English units, hydrologic data within this chapter are in English, rather than metric, units.

We assigned all plots as a control site (above Parker Dam or below Imperial Dam) or as a test site (between Parker and Imperial), then analyzed between-year differences in T/RH and SM values within these two groups using paired t-tests. We then analyzed the between-year differences among the test sites compared to the control sites using one-way repeated measures ANOVA. These analyses were restricted to 1 June–1 August. Analyses were conducted using SAS® Version 9.1 (SAS Institute 2003).

Vegetation

We analyzed the between-year differences among the test sites compared to the control sites using one-way repeated measures ANOVA. These analyses and all descriptive statistics were produced using SPSS® Version 16.0 (SPSS Inc.) software. We excluded vertical foliage density measurements at 5 m from plot center from the analysis so as to have comparable data across years.

Groundwater Levels

We examined the following correlations between piezometer levels and reservoir operations:
1) correlation of the Havasu NE piezometer (control site) with Lake Havasu water levels; and
2) correlation of nine test site piezometers between Parker and Imperial Dams (Ehrenberg, Three Fingers Lake, Walker Lake, Hoge Ranch, Rattlesnake, Clear Lake, Ferguson Wash, Ferguson Lake, and Great Blue Heron) with releases (in cubic feet per second, or cfs) from Parker Dam, which largely regulates streamflow in the lower Colorado River between Parker and Imperial Dams.

Groundwater fluctuations under potential flycatcher habitat are expected to be tied most closely to the water level, or stage, rather than to the streamflow of the Colorado River. The relationship between stage and streamflow is not necessarily linear; however, initial analyses from 2005 indicate it is close enough to a linear relationship to allow a very close match between Parker releases and piezometer water levels. To account for the travel time of river water from Parker Dam, several regression analyses were conducted with time lags varying from zero to four days.

We examined monthly river flow data from below Parker Dam from 2000 to 2008 to determine whether there has been a decrease in water levels since the scheduled implementation of the change in point of diversion from Imperial Dam to above Parker Dam, which began in early 2001.

Reclamation (2000) estimated the expected change in river stage between Parker and Imperial Dams that would result from a 400,000 acre-foot reduction in releases from Parker Dam. In previous reports (McLeod et al. 2007), this expected reduction in river stage was extended using regression equations developed from the piezometer measurements to predict the corresponding change in groundwater level below each habitat polygon. This analysis was not repeated for this report.

In addition to correlating piezometer levels with reservoir operations, we used linear regression to examine potential relationships between average daily piezometer level and average daily soil moisture. These analyses were conducted using the built-in analysis functions of Microsoft Excel. Piezometer water levels were also compared to ground surface to determine whether any inundation or standing water was observed at the piezometer locations.

Groundwater fluctuations are the reflection of various inflows or outflows from the shallow aquifer system below the habitat. Longer-term fluctuations, on the weekly or seasonal scale, are mostly linked to variation in reservoir releases and flow in the Colorado River. Shorter-term fluctuations, those that take place over the course of a single day, are the result of the removal of water from the shallow aquifer through evapotranspiration by riparian habitat. The magnitude of these fluctuations can potentially be used to estimate changes in vegetation density or vegetation cover over time. The magnitude of the daily

evapotranspiration signature was calculated from the difference between the minimum and maximum water levels that occurred during each day, and the median of the daily results was calculated for each month during 2006 (the first full season of data) and 2007. Changes in the magnitude of the evapotranspiration signature over time will be correlated to actual field measurements of vegetation density or cover.

RESULTS

HOBO Logger Maintenance

HOBO loggers have been downloaded three times per year since installation. At each download, we examine the data to determine if there are any problems with data logger function. Data loggers are replaced whenever a potential problem with the sensors is detected. Battery level is also checked at each download, and the battery is replaced if needed.

Piezometer Installation and Maintenance

Table 7.1 lists details on installation parameters for all piezometers. Data from all piezometers were downloaded in December 2005; June and September 2006; February, July, and August of 2007; and February and September of 2008. All pressure transducers except those at Three Fingers Lake and Walker Lake have experienced some data breaks over their lifetime, primarily due to battery failure (Table 7.1). Isolated incidents of battery failure are expected in field equipment, and battery voltage is routinely monitored at the time of each download. However, such widespread and consistent failure appears to be systemic and is currently being addressed with the equipment manufacturer.

Table 7.1. Summary of Piezometer Construction and Data Collection at Habitat Monitoring Sites, Lower Colorado River, 2005–2008*

Site	Depth (ft)	Stickup height (ft)	Date installed	Data breaks	Distance (ft) from habitat

* INA = information not available, N/A = not applicable.

[1] Piezometer destroyed by clearing activity between February and July 2007; replaced 27 March 2008.

[2] Location of original piezometer burned in December 2006; piezometer replaced on 5 July 2007.

In addition to the battery failure incidents that resulted in complete failure of the unit to collect data, some periods of data from Blankenship and Paradise are suspect. The Blankenship pressure transducer began to return anomalous data and stopped collecting data altogether shortly after the August 2007 download. Batteries were changed during the February 2008 download and the unit was restarted. During the September 2008 download, the pressure transducer failed to communicate with the Rugged Reader and after numerous attempts the download process was abandoned. The Paradise pressure transducer stopped collecting data shortly after both the August 2007 download and the February 2008 download; fresh batteries were installed at each download. For the purposes of analysis, all data after August 2007 were disregarded for both Blankenship and Paradise.

In July 2007, a replacement piezometer at the Gila Confluence North station was installed approximately 0.1 mile north of the original location. This station used the original pressure transducer, which was not damaged in the fire; however, a replacement cable was installed. The pressure transducer appears to have been malfunctioning since reinstallation; it is collecting data but there are no fluctuations in the data, and the data do not match the manual measurements. For the purposes of analysis, all post-fire data have been disregarded.

During the 2007 field season, the Cibola Lake piezometer had been cleared and bulldozed, and no trace of the piezometer could be located. On 27 March 2008, a replacement piezometer was installed on an island within Cibola Lake, adjacent to one of the HOBO monitoring sites. As of this report, the station is operational but no data has been downloaded from the site. One attempt was made in October 2008, but there was a hardware compatibility issue with the driver for the serial cable adapter that connects the field laptop to the pressure transducer, thus impeding any download attempts.

Microclimate

2008 Microclimate Descriptive Statistics

Soil moisture, temperature, relative humidity, and vapor pressure parameters from the 15 study sites monitored in 2008 exhibited substantial variation among sites (Table 7.2). Soil moisture varied by a factor of six among the 2008 study sites, from a low of 194.7 mV at Havasu NE to a high of 951.3 at Great Blue Heron.

Mean diurnal temperatures ranged from a low of 28.3°C at Rattlesnake and a high of 37.4°C at Cibola Lake. Mean nocturnal temperatures ranged from a low of 20.2°C again at Rattlesnake and a high of 26.0°C at Ferguson Wash. Mean number of 15-minute intervals above 41°C each day varied from 1.8 at Rattlesnake to 24.7 at Cibola Lake. Mean daily temperature range varied from 21.3°C at Ferguson Lake to 33.3°C at Three Fingers Lake.

Mean diurnal relative humidity ranged from 23.5% at Cibola Lake to 52.6% at Rattlesnake. Mean diurnal vapor pressure was lowest at Cibola Lake (1,047.6 Pa) and highest at Rattlesnake (1,900.9 Pa). Mean nocturnal vapor pressure was lowest at Havasu NE (974.4 Pa) and highest at Rattlesnake (1,683.7 Pa).

Between-year Comparisons of Microclimate Characteristics

Microclimatic characteristics at habitat monitoring sites varied significantly over time at test sites (Cibola Lake, Clear Lake, Ehrenberg, Ferguson Lake, Ferguson Wash, Great Blue Heron, Hoge Ranch, Paradise, Rattlesnake, Three Fingers Lake, and Walker Lake; Table 7.3). At control sites (Blankenship Bend, Gila Confluence North, Havasu NE, Mittry West), only mean nocturnal temperature and nocturnal vapor pressure varied significantly over time. In 2007 and 2008, mean soil moisture increased at both test and control sites. Mean diurnal temperature, mean number of 15 minute intervals above 41°C each day, and mean nocturnal temperature all decreased slightly in 2008 for control sites, but remained about the same as in 2007 for test sites. For both test and control sites, all measures of humidity and vapor pressure decreased in 2007 compared to 2006, but increased in 2008. Except for soil moisture, the changes over time were the same for test sites and controls (right-most column of Table 7.3).

Comparison of Parker/Imperial to Topock: Microclimate

All microclimate parameters except for mean soil moisture were significantly different between Topock Marsh and the habitat monitoring sites (Table 7.4). Topock was cooler and exhibited higher relative humidity and vapor pressure than habitat monitoring sites.

Table 7.4. Comparison of Microclimatic Variables at Habitat Monitoring Sites to Territories at Topock Marsh, 2008*

Response Variable	Habitat Monitoring Sites	Topock Marsh	*P*
N (Temp./Humidity Sensor Arrays)	57	11[1]	N/A
Soil Moisture			
Mean soil moisture (mV)	683.6 (39.7)	783.3 (73.9)	0.301
Temperature/Humidity			
Mean diurnal temperature (°C)	32.9 (0.4)	29.0 (0.6)	<0.001
Mean no. of 15 min. intervals above 41°C each day	13.0 (1.2)	3.1 (1.2)	0.001
Mean nocturnal temperature (°C)	23.6 (0.3)	21.7 (0.5)	0.005
Mean daily temperature range (°C)	25.9 (0.8)	21.6 (0.9)	0.019
Mean diurnal relative humidity (%)	36.8 (1.3)	55.7 (2.5)	<0.001
Mean diurnal vapor pressure (Pa)	1500.4 (46.2)	2,101.1 (73.2)	<0.001
Mean nocturnal relative humidity (%)	50.9 (1.2)	67.2 (2.6)	<0.001
Mean nocturnal vapor pressure (Pa)	1,441.1 (28.9)	1,760.4 (48.0)	<0.001

* Soil moisture and temperature/humidity values are means (standard error in parentheses). N/A = data not available or not applicable. The analysis was restricted to 6 May–31 July 2008.

[1] This includes nine territory locations and two HOBOs placed near the piezometer.

Vegetation Measurements

Vegetation characteristics varied widely both between and within the selected habitat monitoring sites (Table 7.5). Average canopy height ranged from 3.5 m (Three Fingers Lake) to 10.4 m (Ehrenberg), and average canopy closure ranged from 69.9% (Ehrenberg) to 98.0% (Ferguson Lake). Measures of other habitat characteristics were similarly variable. Vertical foliage profiles for each site are shown in Figure 7.1. Sites typically exhibited the densest foliage within 4–5 m of the ground, and the majority of vegetation within 2–3 m of the ground typically consisted of dead branches.

Between-year Comparisons of Vegetation Characteristics

Average values of canopy height, canopy closure, woody ground cover, percent of the basal area in each plot that consisted of native vegetation, and live and dead stems in <2.5 cm, 2.5–8.0 cm, and >8 cm dbh size categories for both test and control sites by year are shown in Table 7.6. Repeated measures ANOVA comparing these variables between years showed an overall between-year difference in canopy closure ($P = 0.001$), woody ground cover ($P < 0.001$), and number of dead stems 2.5–8 cm dbh ($P = 0.003$) for all plots combined. There were no significant interactions between canopy closure or number of dead stems 2.5–8 cm dbh and location (test vs. control sites), meaning the change in these variables between years among test sites was not significantly different from the change at control sites. Across all sites, canopy closure decreased between 2005 and 2006 and then increased in 2007 and 2008 to values higher than those recorded in 2005. The number of dead stems 2.5–8 cm dbh was lower in 2006 and 2007 than in 2005 or 2008. Percent woody ground cover was higher in 2008 than in previous years.

Table 7.5. Summary of Vegetation Characteristics at Habitat Monitoring Sites, Lower Colorado River, 2008*

There was a significant interaction between year and location for woody ground cover ($P = 0.002$). Average woody ground cover increased at control plots between 2005 and 2006 and then decreased in 2007, while it did not change at test plots across those years.

Repeated measures ANOVAs for vertical foliage in each meter interval showed no significant between-year differences in live vegetation but showed between-year differences for the first, second, third, and fourth meter intervals above the ground for dead vegetation. In all cases, density of dead vegetation was higher in 2008 than in 2007. There was a significant interaction ($P = 0.037$) between live vertical foliage density and location (test vs. control sites) for the fourth meter interval, but there was no clear pattern, with density increasing at control plots in years it decreased at test plots, and vice versa. There was also a significant interaction ($P < 0.001$) between dead vertical foliage density and location for the first meter interval, with the density of dead vegetation increasing more in 2007 and 2008 at control plots relative to test plots.

Groundwater Monitoring

Overview of Piezometer Groundwater Levels

More than two full years of data have been collected at 15 of the 16 piezometers (excluding Topock Marsh, which has nearly two full years of data), with the exception of the data breaks noted in Table 7.1.

The piezometer hydrographs generally exhibit some common characteristics. Two general trends, a weekly trend and a daily cycle, are apparent. Groundwater levels were lowest during the afternoon hours and on weekends, while high groundwater levels were observed in early morning hours and in the middle of the week. The weekly trend is the result of reservoir operation and changes in river water levels; the daily trend is the result of evapotranspiration of water from the aquifer. Both trends are useful for analysis.

A third general trend, a seasonal pattern, has appeared in the hydrographs as multiple years of data have been recorded. In the majority of the hydrographs, the lowest groundwater levels occurred in the winter and highest groundwater levels occurred in the spring (Table 7.7). Average monthly groundwater level ranges from inundated conditions at Mittry West to over 6 feet below ground surface at Paradise, with an average seasonal water level change of just over 2 feet. Hydrographs for all piezometers are included in Appendix E. For 2008, the data trend is very similar to that of previous years, with some sites having slightly higher and lower maximum and minimum groundwater levels.

Table 7.7. High and Low Average Monthly Water Depths Recorded at Piezometers at Habitat Monitoring Sites, August 2005–August 2008

Location	Shallowest water level (ft bgs)	Month occurred	Deepest water level (ft bgs)	Month occurred
Topock	1.52	March	2.1	September
Blankenship Bend	1.99	June	3.70	December

[1] Data from two locations

Correlation of Piezometer Groundwater Levels with Reservoir Releases

Lake Havasu Water Levels – There is a strong correlation ($R^2 = 0.96$) between water levels in Lake Havasu as measured by the USGS and groundwater levels below the habitat as measured in the Havasu NE piezometer (Figure 7.2). Data prior to August 2007 (before erroneous data collection) indicated that the piezometer at Blankenship Bend appears to be too far upstream to be strongly correlated with lake levels, showing a correlation through the same period with an R^2 value of only 0.09.

Colorado River Water Levels – Data were collected between August 2005 and September 2008 in hourly intervals and averaged by the day. The "best fit" time lag varied from two days for the upstream piezometers (Hoge Ranch, Cibola, Ehrenberg, Paradise and Three Fingers Lake) to three days for the downstream piezometers (Rattlesnake, Clear Lake, Ferguson Lake, Ferguson Wash, and Great Blue Heron). The best fit R^2 statistics varied from 0.71 to 0.94 (Table 7.8). Piezometer levels at Walker Lake had no correlation ($R^2 = 0.15$–0.16) to releases from Parker Dam. Additionally, the relationship between piezometer levels at Mittry West and releases from Imperial Dam was examined for the entire time period (May 2005–September 2008). There was no correlation between releases and water levels (best $R^2 = 0.003$).

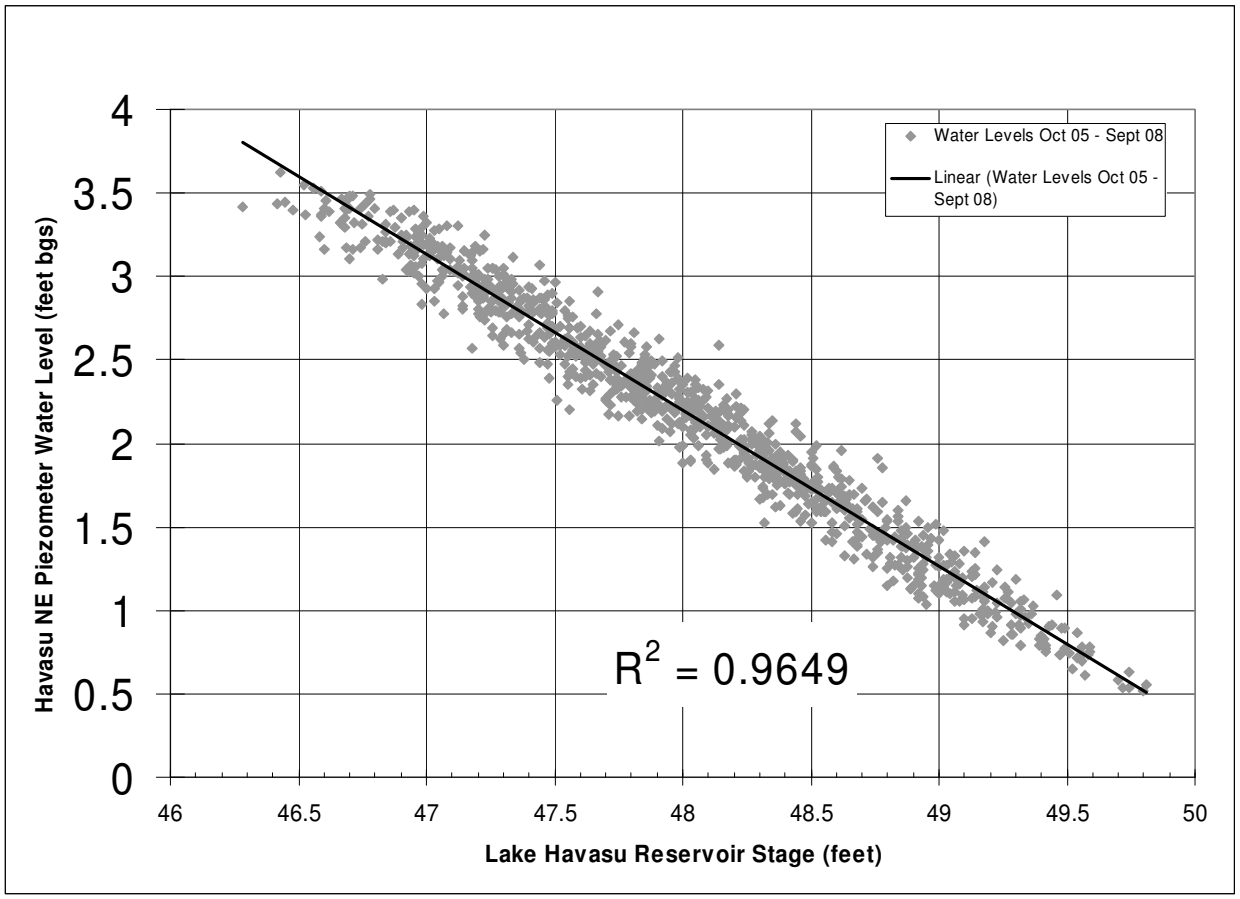

Figure 7.2. Correlation of Havasu NE piezometer and Lake Havasu water levels, October 2005–September 2008. Line shows linear regression.

Table 7.8. Correlation (R^2 Statistic) of Parker Dam Daily Releases (cfs) with Average Daily Groundwater Levels (feet bgs) of Piezometers at Habitat Monitoring Sites, September 2006–September 2008*

Site	Time Lag				
	None	1 day	2 days	3 days	4 days
Ehrenberg	0.82	0.92	0.93	0.85	0.78
Cibola Lake	0.26	0.45	0.66	0.47	0.29
Three Fingers Lake	0.78	0.87	0.94	0.84	0.77
Walker Lake	0.16	0.16	0.15	0.15	0.16
Paradise	0.69	0.79	0.91	0.82	0.72

Clear Lake	0.77	0.81	0.89	0.92	0.87
Ferguson Lake	0.68	0.72	0.88	0.93	0.83
Ferguson Wash	0.56	0.60	0.68	0.71	0.63
Great Blue Heron	0.67	0.71	0.79	0.86	0.83

* Shaded cells indicate best correlation.

Planned Declines in Parker Releases – An examination of monthly river flows below Parker Dam from 2000 to 2008 (Table 7.9) revealed there has been a noticeable decline in reservoir releases during most months. While there is moderate variation, average monthly flow decreased from 2001 (the year prior to the scheduled change in point of diversion) to present, with the percent decrease ranging from 13.4% in January 2008 to 31.7% in December of 2007. The decreases occurred throughout the year except for February–April. March experienced an increase of average flow for 2008; releases for February and April were roughly equivalent to those in 2001.

Table 7.9. Average Monthly Flows (cfs) Below Parker Dam, 2000–2008

Correlation of Piezometer Groundwater Levels with Soil Moisture Measurements

Linear regressions between the average soil moisture measurements and the average daily groundwater level in the piezometer for that site show little to no correlation between these two variables (R^2 = 0.0–0.50; Table 7.10). Analysis included all available data from 2005 to 2008.

Table 7.10. Results of Linear Regression Between Average Daily Piezometer Groundwater Levels and Soil Moisture at Habitat Monitoring Sites, Lower Colorado River, 2005–2008

Site	Number of data points	Range of soil moisture values (mV)	Median soil moisture value (mV)	R^2
Blankenship Bend	15	393–1070	960	0.24

Topock	27	864–975	908	0.01

Presence of Standing Water

Data from Gila Confluence North indicate that the piezometer location was inundated from 18 to 20 October 2005 to a depth up to 1.4 feet. Data from Mittry West indicate that piezometer location was inundated four times in three different years: 22 April–2 May 2006 to a depth up to 0.2 feet; 5 April–5 May 2007; 20 March–19 May 2008; and 24–25 May 2008. Data from two other sites, Three Fingers Lake and Rattlesnake, also indicated possible inundation, but repeated differences between data logger and manual measurements suggest these data may not be accurate. Topock did not appear to have encountered standing water based on piezometer measurements.

Evapotranspiration Signature

Nearly all the sites exhibit a typical seasonal trend in evapotranspiration, with the magnitude of the daily evapotranspiration signature peaking between June and September (Tables 7.11 and 7.12). The Ehrenberg piezometer exhibited duplicate measurements occurring in a 23-hour cycle beginning in November 2005; this equipment malfunction was investigated with the manufacturer but was not able to be resolved until July 2007. Ehrenberg data are not presented here for 2006 or 2007. The difference between 2006 and 2007 is shown in Table 7.13.

DISCUSSION

Microclimate

Comparison of Parker/Imperial to Topock

Most microclimatic variables at the combined habitat monitoring sites differed significantly from those at Topock Marsh. The habitat monitoring sites were lower in elevation and at lower latitudes than Topock and therefore were more likely to be warmer, an expectation confirmed by all measures of diurnal temperature parameters compared in Table 7.4.

Between-year Comparisons of Microclimate Characteristics

Comparisons of microclimate characteristics among 2005, 2006, 2007, and 2008 at the habitat monitoring sites indicated generally hotter and more humid conditions in 2006 than in the other years. The interannual changes were generally similar between test and control sites, suggesting that changes in temperature and humidity conditions may have been regional, rather than being influenced by changes in river operations. Soil moisture was lower in 2006 than in 2005 or 2007, and while this pattern was exhibited at both test and control sites, the interannual change was greater at control than at test sites. In 2008, soil moisture at test sites increased while it remained the same at control sites. This suggests that local conditions, in addition to regional climate, may have influenced soil moisture. The role of river flows in influencing soil moisture within the sites is still unclear, given that no strong relationship was

found between piezometer levels and soil moisture (see Correlation of Piezometer Groundwater Levels with Soil Moisture Measurements below).

Vegetation

Between-year differences across all sites were noted for canopy closure, woody ground cover, and number of dead stems 2.5–8 cm dbh. None of these variables showed unidirectional trends from 2005 to 2008, suggesting that the differences are not indicative of long-term, regional habitat changes during that time period. Changes in canopy closure could be caused by changes in overall weather conditions between the years or could be the result of systematic observer variation.

Woody ground cover showed an overall increase in 2008; the number of dead stems 2.5–8 cm dbh was higher in 2008 and 2005 than in the intervening years; and the vertical density of dead vegetation was greater in 2008 than in 2007 within 4 m of the ground. The increases in these variables in 2008 suggest there may have been more dead vegetation in 2008. No corresponding change in the number of live stems or canopy closure was observed, and additional years of monitoring will help determine whether the changes observed in 2008 represent a real increase in the amount of dead vegetation.

Few variables showed changes that were specific to control or test sites. Ground cover did not differ between 2005 and 2007 at test locations but increased at control plots in 2006 and then decreased in 2007. It is not clear whether this represents actual changes in the amount of woody ground cover or whether it is a result of observer variation. Vertical foliage counts did not show any consistent differences between control and test locations. Measurable changes in vegetation as a response to water availability may take several years to develop, and future years of monitoring will help determine whether water diversions are affecting potential flycatcher habitat.

Groundwater Levels

Piezometer Groundwater Levels

The general daily and weekly cycles that were attributed to evapotranspiration and river operations, respectively, in the 2005 data are still visible in the 2006–2008 data. Groundwater levels drop during afternoon hours and on the weekends, while higher groundwater levels occur in early morning hours and in the middle of the week. The daily small-scale groundwater level fluctuations are caused by evapotranspiration of plants. During the day, the riparian vegetation removes water from aquifer storage, which is then replenished as evapotranspiration lessens near the end of the day. These fluctuations occur at similar times of day regardless of distance downstream from Parker Dam and are thus unlikely to be the result of daily fluctuations in releases, which would exhibit a lag effect with increasing distance downstream. In addition, similar daily fluctuations occur at the control sites both upstream and downstream of Parker Dam, and follow typical evapotranspiration patterns (White 1932, Freeze and Cherry 1979).

The seasonal cycle in groundwater levels mirrors the seasonal fluctuation in river flow. This is driven primarily by the operational decrease in releases from Parker Dam. Evapotranspiration would be expected to decrease during the winter months, which should result in higher river and groundwater levels during the winter; however, this trend is not observed. Any seasonal effect of evapotranspiration appears to be overwhelmed by operations at Parker Dam.

Several anomalous hydrograph features deserve discussion:

Walker Lake – The Walker Lake piezometer recovered slowly from two apparent inundations in the late summer of 2005 and went through a period of declining groundwater levels until the 5 December 2005 download. From the point of restart, this piezometer began to show the same general seasonal trend as seen in the other piezometers, with a seasonal high occurring in winter 2006 and seasonal low occurring in spring 2006. Groundwater levels, however, have continued to drop from the seasonal high spring levels to levels more like those first recorded before the summer 2005 inundation, suggesting this lower groundwater level is closer to the seasonal low than that recorded in the winter 2006. We speculated in the 2006 report that Walker Lake represented a backwater area that gets periodically inundated, but otherwise does not respond strongly to fluctuations in the Colorado River. However, since the spike in summer 2005, the seasonal pattern appears to match the pattern at most of the piezometer locations between Parker and Imperial dams, including Rattlesnake, Ferguson Lake, and Clear Lake. The spike, which we speculated may have been an inundation of a backwater lake, does not appear to have repeated.

Mittry West – While the hydrograph for the Mittry West piezometer was almost flat from installation through December 2005, the data now show a seasonal trend. A peak in groundwater level occurred on 29 April 2006, from which point water levels declined into the summer months. Weekly fluctuations and daily fluctuations are not as apparent on the rising leg of the 2006 seasonal curve, but reappear on the declining leg of the curve. This may be attributed to the onset of evapotranspiration with the regrowth of vegetation in the immediate area surrounding the piezometer. Because of the inexplicable flat data from the first data downloads, we considered reinstalling the Mittry West piezometer at a different location within the habitat polygon. It now appears that this piezometer is functioning properly, and the flat data likely reflect the true groundwater levels at the site. The data have remained consistent through 2008.

Havasu NE – Daily and weekly changes in groundwater level are apparent in the Havasu NE hydrograph; however, there is no seasonal trend common in the other hydrographs. This lack of a seasonal trend at the Havasu NE piezometer can be attributed to the highly regulated water level at Lake Havasu.

Gila Confluence North, Paradise, and Blankenship – These piezometers appear to be malfunctioning or inoperative. Gila Confluence North has been returning nearly flat data since its relocation in July 2007, which is drastically different from the data collected prior to reinstallation. It is unclear whether it is a hardware or installation problem. Paradise has had massive battery failure since August 2007. It will likely need to be replaced, although the systemic problems with battery life are also being investigated with the manufacturer. Blankenship, as mentioned, began returning erratic measurements in August 2007. It has not functioned properly since and will no longer communicate with our download interface. It will likely need to be replaced.

Topock – Nearly two years of data exist for Topock. Data from 2007 showed high groundwater levels in spring, followed by declining water levels through the summer. Data gaps in 2008 make it difficult to determine whether this pattern continued.

Correlation of Piezometer Groundwater Levels with Reservoir Releases

Regression analyses indicated that, as would be expected, piezometer readings were best correlated with flow release data that had been time-lagged to allow for the progression of releases downstream.

The most upstream site included in the analyses (Ehrenberg) showed a two-day lag, while the most downstream site (Great Blue Heron) showed a three-day lag.

Correlation of Piezometer Groundwater Levels with Soil Moisture Measurements

With two to three years of data at most sites, we have not found a linear relationship between piezometer water levels and soil moisture measurements at the subset of habitat monitoring sites for which we have complete data sets. The highest correlations between groundwater levels and soil moisture occurred at sites where soil moisture is relatively high and surface water is sometimes present, suggesting that soil moisture is most strongly affected by groundwater when distance to groundwater is shallow. Soil texture influences the capillary rise of groundwater from a shallow aquifer, and variability in soil texture among sites may confound the relationship between piezometer groundwater levels and soil moisture. Soil samples collected during various field activities over the last three years are currently being analyzed for soil texture. Future analyses will examine soil texture and incorporate these data into a more complex analysis of the influence of groundwater levels on soil moisture.

Presence of Standing Water

Standing water appears to be consistent at Mittry West in the spring but does not appear to be a factor at any other site. Based on anecdotal observations, Topock was considered likely to experience inundation, and we expected such inundation could show up during the piezometer monitoring. However, that has not yet occurred, despite surface water being observed less than 10 m from the piezometer during May 2008.

Evapotranspiration Signature

The usefulness of the evapotranspiration signature is in assessing the relative change in evapotranspiration, and thus vegetation density, at a given site over time. With only two years of data, it is not yet useful to look for trends at individual sites. However, the comparison of 2006 to 2007 data suggests that variations in temperature between the years may need to be incorporated into the future analysis, as these could also account for differences in evapotranspiration signature. Almost all of the sites exhibited less evapotranspiration during the latter half of 2007; such a regional change is more suggestive of climate variation than vegetation growth or decline at individual sites.

FIELD DATA FORMS

Willow Flycatcher Survey and Detection Form (revised April, 2004)

Site Name_____ State_____ County _____
USGS Quad Name _____ Elevation _____ feet / meters (circle one)

Is copy of USGS map marked with survey area and WIFL sightings attached (as required)? ☐ *Yes* ☐ *No*

Site Coordinates: Start: N_____ E_____ UTM Datum_____ (NAD27 preferred)
Stop: N_____ E_____ UTM Zone _____

***** Fill in additional site information on back of this page *****

Survey # / Observer(s) (Full Name)	Date (m/d/y) Survey time	Number of Adult WIFLs	Estimated Number of Pairs	Estimated Number of Territories	Nest(s) Found? Y or N	Cowbirds Detected? Y or N	Presence of Livestock, Recent sign, If Yes, Describe Y or N	Comments about this survey (e.g., bird behavior, evidence of pairs or breeding, number of nests, nest contents or number of fledges seen; potential threats)
1_____	Date Start Stop Total hrs ____							
2_____	Date Start Stop Total hrs ____							
3_____	Date Start Stop Total hrs ____							
4_____	Date Start Stop Total hrs ____							
5_____	Date Start Stop Total hrs ____							
Overall Site Summary (Total **resident** WIFLs only) Total survey hrs_____		Adults	Pairs	Territories	Nests	Were any WIFLs color-banded? Yes No If yes, report color combination(s) in the comments section on back of form		

Reporting Individual _____ Date Report Completed _____
US Fish and Wildlife Service Permit #_____ AZ Game and Fish Department (or other state) Permit # _____

Submit original form by August 1st. Retain a copy for your records.

Fill in the following information completely. Submit original form by August 1st. Retain a copy for your records.

Reporting Individual _____ Phone # _____
Affiliation _____ E-mail _____
Site Name _____ Date Report Completed _____

Did you verify that this site name is consistent with that used in previous years? Yes / No (circle one)
If name is different, what name(s) was used in the past? _____
If site was surveyed last year, did you survey the same general area this year? Yes / No If no, summarize in comments below.
Did you survey the same general area during each visit to this site this year? Yes / No If no, summarize in comments below.

Management Authority for Survey Area (circle one): Federal Municipal/County State Tribal Private
Name of Management Entity or Owner (e.g., Tonto National Forest) _____

Length of area surveyed: _____ (specify units, e.g., miles = mi, kilometers = km, meters = m)

Vegetation Characteristics: Overall, are the species in tree/shrub layer at this site comprised predominantly of (check one):

☐ Native broadleaf plants (entirely or almost entirely, includes high-elevation willow)

☐ Mixed native and exotic plants (mostly native)

☐ Mixed native and exotic plants (mostly exotic)

☐ Exotic/introduced plants (entirely or almost entirely)

Identify the 2-3 predominant tree/shrub species: _____

Average height of canopy (Do not put a range): _____ (specify units)

Was surface water or saturated soil present at or adjacent to site? Yes / No (circle one)
Distance from the site to surface water or saturated soil: _____ (specify units)

Did hydrological conditions change significantly among visits (did the site flood or dry out)? Yes / No (circle one)
If yes, describe in comments section below.

Remember to attach a copy of a USGS quad/topographical map (REQUIRED) of the survey area, outlining the survey site and location of WIFL detections. Also include a sketch or aerial photograph showing details of site location, patch shape, survey route in relation to patch, and location of any willow flycatchers or willow flycatcher nests detected. Such sketches or photographs are welcomed, but DO NOT substitute for the required USGS quad map. Please include photos of the interior of the patch, exterior of the patch, and overall site and describe any unique habitat features.

Comments (attach additional sheets if necessary)

SWFL General Site Description

[Complete at least 3 times during season: early (10–25 May), mid-season (10–25 June), and late season (10–25 July)]

General Info

Study Area: _____ **Survey Site:** _____ **Date:** _____

Observer(s): _____ **early**_____ **mid**_____ **late**_____ **other**_____

Vegetation

Vegetation at site: >90% native 50–90% native 50–90% exotic >90% exotic

Canopy closure: <25% 25–50% 50–70% 70–90% >90%

Overstory height (m): _____ **Dominant overstory species:** TASP SAGO SAEX POFR Other _____

Understory height (m): _____ **Dominant understory species**: TASP SAGO SAEX PLSE Other _____

Other vegetation types present (e.g., cattail)? Yes No

If yes, type of vegetation: _____ **percentage of site:**_____
type of vegetation: _____ **percentage of site:**_____
type of vegetation: _____ **percentage of site:**_____

Hydrology

% of site inundated: _____

Describe type of surface water (e.g., open marsh, surface water within woody vegetation, stream, etc):
_____

Average depth of surface water:
toes (<5cm) ankles (5-15 cm) calves (15-40 cm) knees (40-60 cm)
thighs (60-80 cm) waist (100 cm) too deep to wade (>100 cm)

% of site with saturated soils (do not include inundated areas in percentage!): _____

% of site with damp soils (do not include inundated or saturated areas): _____

If not inundated or saturated, distance (m) to standing water or saturated soil:_____

How was distance determined? Visually estimated in field Measured in field using GPS
Measured from aerial photograph Other _____

Describe type of nearest surface water: _____

Narrative and Pictorial Description

Does this description cover the entire site? Y N **If not, which portion is described?**_____
_____

On the reverse, sketch and label the locations of the major vegetation types you observed. Delineate marshes, open areas, and other habitat that may be unsuitable for flycatchers. If water was present, show its location.

Give a narrative description of the site, including adjacent habitats:

		Eggs
		Nestlings
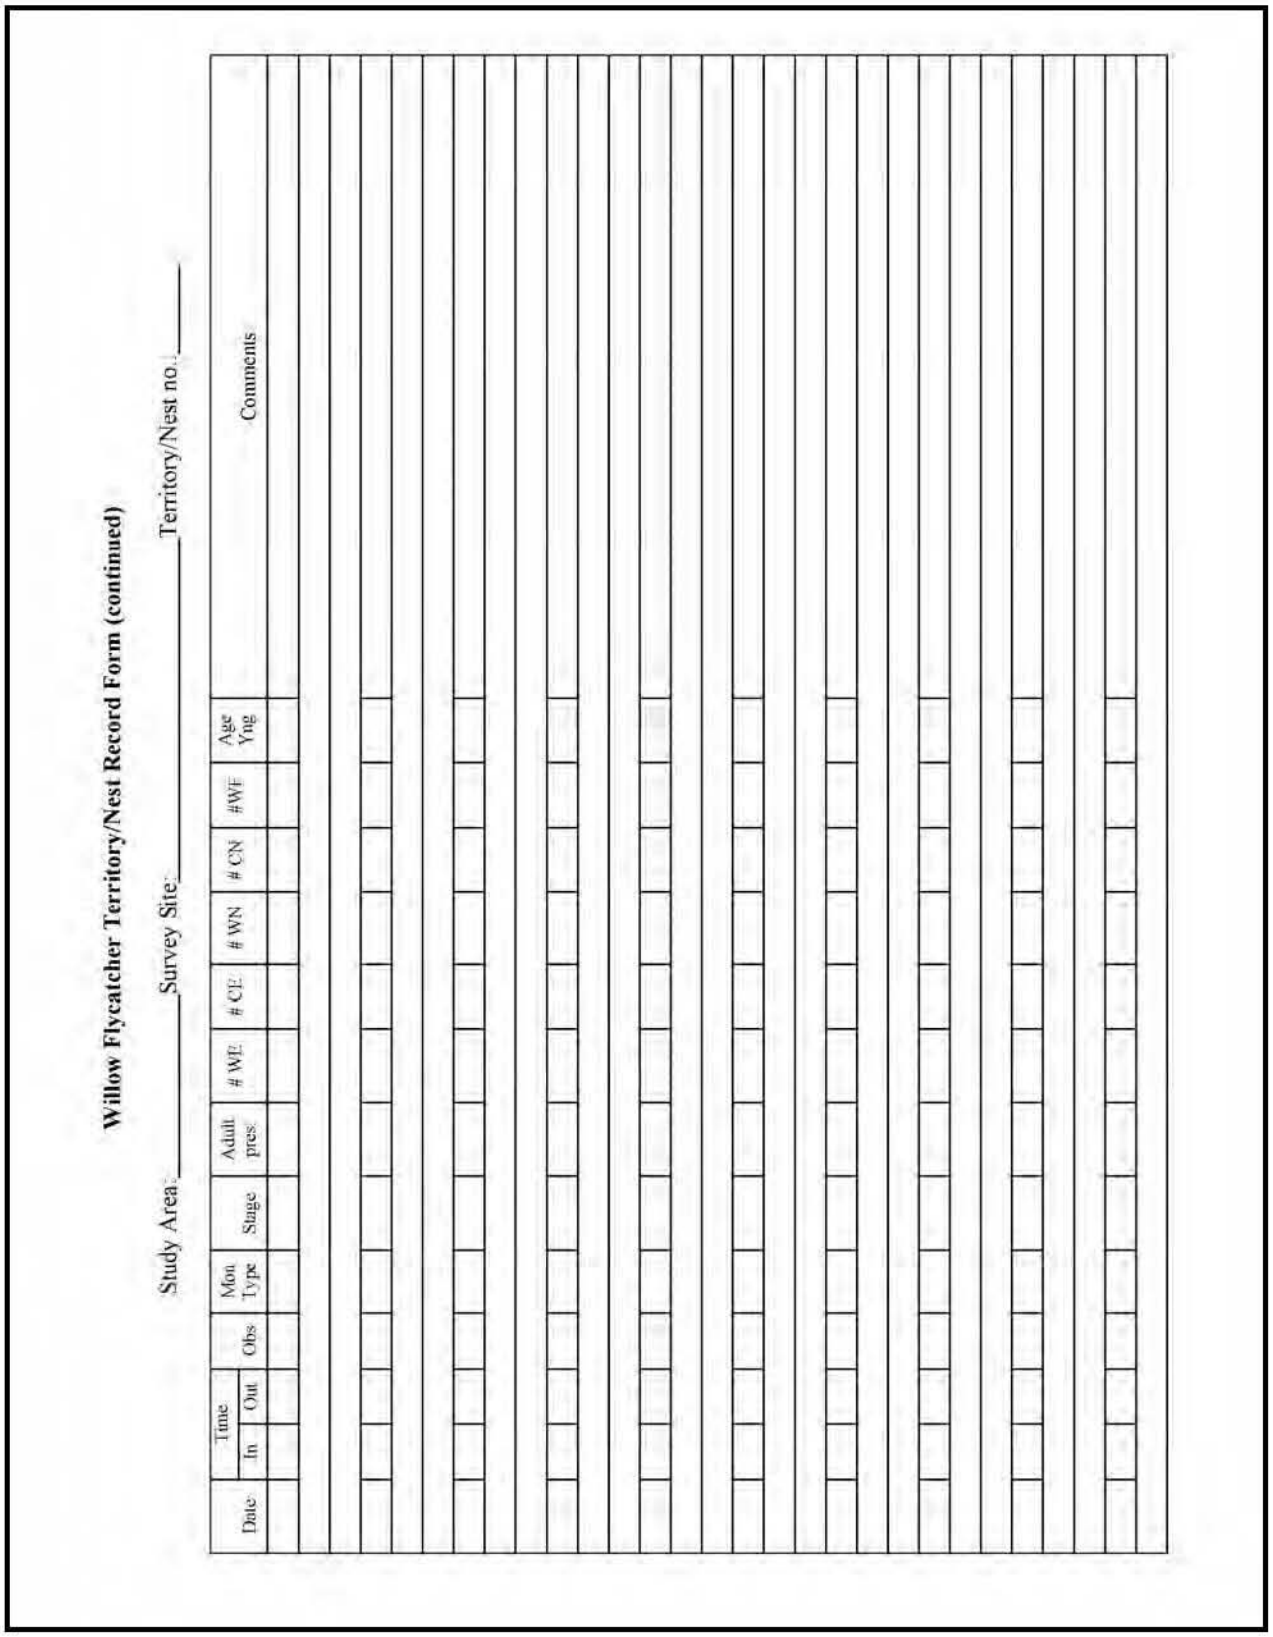
		Fledgling

Outcome (Record code & describe)**:**_____:_____

_____

_____



_____

Outcome codes:
UN= unknown; **FY**= fledged young, with at least one young seen leaving or in the vicinity of nest; **FP**= fledged young, as determined by parents behaving as if dependent fledgling(s) nearby; **FU**= suspected fledging of at least one young; **FC**= fledged at least one host young with cowbird parasitism; **FD**= Nest partially depredated with confirmed fledging of at least one young; **PO**= predation observed; **PE**= probable predation, nest empty and intact; **PD**= probable predation, damage to nest structure; **AB**= nest abandoned prior to egg(s) being laid; **DE**= deserted with egg(s) or young; **PA**= parasitized, host attempted to raise cowbird young. No host young were fledged from the nest; **WE**= failure due to weather; **AD**= failure, entire clutch addled/infertile; **OT**= failure due to other, or unknown, causes.

Mayfield Success

(WIFL) Period	# Exposure days	Success
Egg Laying		
Incubation		
Nestling		

Mayfield success codes: **S**= successful; **D**= depredated; **U**= status unknown/nest occupied- fate unknown; **M**= mortality other than predation; **A**= abandoned with host egg(s) or young; **Z**= abandoned, no (zero) eggs laid.

PREFACE

This document is one of the deliverables submitted to the U.S. Bureau of Reclamation under contract # GS-10F-0209L to complete Southwestern Willow Flycatcher (*Empidonax traillii extimus*) studies along the lower Colorado River and tributaries in 2008. The document comprises a list of all sites surveyed for willow flycatchers in 2008 and the UTM coordinates (Zone 11, NAD 83) of the centroid of each site (Table 1), along with a compilation of aerial photographs. These aerial photographs include the location, identity, and breeding status of each willow flycatcher detected at study areas where resident flycatchers were detected during 2008 (Figure 1). For additional information regarding methodology and willow flycatcher surveys, demography, and ecology along the lower Colorado River and tributaries in 2008 refer to:

> McLeod, M.A., and T.J. Koronkiewicz. 2009. Southwestern Willow Flycatcher surveys, demography, and ecology along the lower Colorado River and tributaries, 2008. Annual report submitted to U.S. Bureau of Reclamation, Boulder City, NV by SWCA Environmental Consultants, Flagstaff, AZ. 153 pp.

This document is intended for use only by the U.S. Fish and Wildlife Service, the U.S. Geological Survey, Nevada Division of Wildlife, California Department of Fish and Game, and the Arizona Game and Fish Department. Specific locations of Southwestern Willow Flycatcher territories and nests may be considered by some agencies as sensitive information. Therefore, this document is not intended for general distribution. Please contact the U.S. Bureau of Reclamation and U.S. Fish and Wildlife Service for permission to copy and distribute this document.

Color Leg Band Combination Codes:

Color-band codes used on each aerial photograph follow the conventions presented below:

Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band and color-band designations for right and left legs are separated with a colon. **EE** = electric yellow federal band, **PU** = pumpkin federal band, **XX** = standard silver federal band, **Bs** = blue federal band, **R** = red, **D** = dark/navy blue, **B** = light blue, **K** = black, **V** = violet, **Z** = gold, **Y** = yellow, **G** = green, **W** = white, **O** = orange, **UB** = unbanded, **(M)** = metal pin striped band.

Nest and Willow Flycatcher Location Codes:

Nest and willow flycatcher location codes on each aerial photograph follow the conventions presented below:

Blue	the approximate use area center for individual willow flycatchers detected at the site for less than 7 days
Yellow	a willow flycatcher nest location
Red	the approximate territory center for a single, territorial willow flycatcher detected at the site for 7 or more days
Green	the approximate territory center for a willow flycatcher pair for which no nesting was confirmed

All locations on the aerial photographs were based on UTM coordinates (Zone 11, NAD 83) obtained in the field in 2008 using a Garmin Rino 110 GPS unit.

Re: SW Willow Flycatcher Studies 2011
T&E Species Permit TE028605-4, Final Permit Report Deliverable

Ms. McCarthy:

In fulfillment of SWCA Environmental Consultant's Federal Fish and Wildlife permit (TE028605-4) deliverable requirement with your department, please find enclosed on CD an annual report titled *Southwestern Willow Flycatcher Surveys, Color-banding and Nest Monitoring along the Lower Colorado River and Tributaries in Nevada, California, Arizona, and Utah, 2011*. This report details all of our Southwestern Willow Flycatcher studies conducted in California in 2011, and is presented in a site-by-site format to facilitate locating information of interest. Please note that only presence/absence surveys were conducted under this permit in California (see Chapter 1).

No field activities for the Desert Tortoise (*Gopherus agassizii*) were conducted in 2011 in California.

If you or your department requires any additional information, please do not hesitate contacting me directly: (928) 774-5500 ext. 4201; tkoronkiewicz@swca.com.

Many thanks for your continuing support, sincerely,

Tom Koronkiewicz

Re: SW Willow Flycatcher Studies 2011
T&E Species Permit TE028605-4, Final Report Deliverables

Ms. Tharratt:

In fulfillment of SWCA Environmental Consultant's Federal Fish and Wildlife permit deliverable requirement with your department, please find enclosed on CDs the annual report titled *Southwestern Willow Flycatcher Surveys, Demography, and Ecology along the Lower Colorado River and Tributaries, 2011;* and the confidential annual report, *Aerial Photographs of Southwestern Willow Flycatcher Nest and Territory Locations along the Virgin and Lower Colorado River Regions, 2011.* These reports detail all of our Southwestern Willow Flycatcher studies conducted in southern Nevada and California in 2011 and are part of our final deliverable to U.S. Bureau of Reclamation. They are supplemental to our annual report delivered to your department in December 2011. Both reports are presented in a site-by-site format to facilitate locating information of interest.

If you or your department requires any additional information, please do not hesitate contacting me directly: (928) 774-5500 ext. 4201; tkoronkiewicz@swca.com.

Many thanks for your continuing support, sincerely,

Tom Koronkiewicz

EXECUTIVE SUMMARY

The Southwestern Willow Flycatcher (*Empidonax traillii extimus*), listed as federally endangered in 1995, breeds in dense, mesic riparian habitats at scattered, isolated sites in New Mexico, Arizona, southern California, southern Nevada, southern Utah, southwestern Colorado, and, at least historically, extreme northwestern Mexico. Historical breeding records and museum collections indicate a sizable population of Southwestern Willow Flycatchers may have existed along the extreme southern stretches of the lower Colorado River region. Factors contributing to the decline of flycatchers on the breeding grounds include loss, degradation, and/or fragmentation of riparian habitat; invasion of riparian habitat by nonnative plants; and brood parasitism by Brown-headed Cowbirds (*Molothrus ater*).

Willow flycatcher studies have been conducted along the Virgin and lower Colorado Rivers and tributaries annually since 1996, in compliance with requirements set forth by the U.S. Fish and Wildlife Service (USFWS) regarding U.S. Bureau of Reclamation (Reclamation) routine operations and maintenance along the lower Colorado River. Biological Assessments and the resulting Biological Opinions on operations and maintenance were prepared as steps to developing a Multi-Species Conservation Program (MSCP) for long-term endangered species compliance and management in the historical floodplain of the lower Colorado River (LCR). The LCR MSCP was signed in April 2005, and implementation of the program began in October 2005. The LCR MSCP calls for continued surveys and monitoring of willow flycatchers along the lower Colorado River. SWCA Environmental Consultants (SWCA) was contracted by Reclamation to continue surveys, monitoring, and demographic and ecological studies of the Southwestern Willow Flycatcher in suitable and/or historical riparian and wetland habitats throughout the Virgin and lower Colorado River regions in 2011.

Reclamation and USFWS completed a separate consultation on the potential effects to threatened and endangered species from implementation of surplus guidelines through 2016 and an annual change in the point of diversion for up to 400,000 acre-feet of California apportionment water for 75 years. The point of diversion, previously located below Parker Dam, would change to a point above Parker Dam. These changes in water regulation could cause a drop in floodplain groundwater levels of 1.55 feet (0.47 m) or less and have the potential to modify riparian habitats below Parker Dam. A Biological Opinion for Interim Surplus Criteria, Secretarial Implementation Agreements, and Conservation Measures was issued in January 2001 and required monitoring of 150.5 ha of existing, occupied Southwestern Willow Flycatcher habitat between Parker and Imperial Dams. In 2004, Reclamation biologists initiated studies of the microclimate within potentially affected areas. In 2005, these studies were continued and expanded by SWCA to address how the hydrological changes might affect riparian habitats along the Parker to Imperial reach.

Following the breeding season of 2008, USFWS and Reclamation initiated discussions regarding the declining number of willow flycatcher territories at Topock Marsh, the importance of the flycatcher population in the Topock area to flycatcher conservation along the LCR, and possible measures to enhance flycatcher habitat at Topock. A plan was developed to pump water into a portion of the flycatcher breeding habitat at Topock beginning in February or March and continuing into the flycatcher breeding season. Water delivery commenced 1 March 2011 and continued into July. Baseline conditions of vegetation, microclimate, and hydrology in the target area were documented in 2009 and 2010, and these studies were continued in 2011 to document conditions during the water delivery period.

SWCA was retained by Nevada Department of Wildlife (NDOW) in 2011 to complete flycatcher surveys, site descriptions, nest monitoring and color-banding at Key Pittman Wildlife Management Area, River Ranch, and Warm Springs Natural Area. We also completed surveys for Yellow-billed Cuckoos at these study areas.

Approximately 100 sites are included in the Reclamation study of flycatchers along the Virgin and lower Colorado Rivers, but a portion of the sites are surveyed biennially rather than annually. In 2011, we completed presence/absence surveys, following a 5-survey protocol, and site descriptions at a subset of the 100 sites. At study areas where territorial flycatchers were detected in 2011, we searched for nests in all areas occupied by territorial flycatchers; monitored willow flycatcher nests to document nest fate, brood parasitism, and causes of nest failure; and color-banded and resighted as many willow flycatchers as possible to determine the breeding status of territorial flycatchers and document movement and recruitment. We also measured characteristics of vegetation and microclimate in occupied territories at one study area.

We used recorded broadcasts of willow flycatcher song and calls to elicit responses from willow flycatchers at 59 Reclamation sites, ranging in size from <1 to 38 ha, along the Virgin and lower Colorado Rivers and tributaries from Pahranagat National Wildlife Refuge (NWR), Nevada, south to Yuma, Arizona between 15 May and 24 July 2011. We detected willow flycatchers on at least one occasion at 47 of these sites. Breeding or resident flycatchers were detected at 13 sites within the Pahranagat NWR, Mesquite, Mormon Mesa, and Muddy River, Nevada; and Topock Marsh and Bill Williams River NWR, Arizona, study areas. South of Bill Williams, 154 willow flycatcher detections were recorded between 15 May and 20 June; no flycatcher detections were recorded at any of these sites after 20 June. Monitoring results suggest these flycatchers were not resident, breeding individuals and were most likely spring migrants.

We completed broadcast surveys for flycatchers at 3 sites and monitored an additional 17 sites within the three NDOW study areas and detected breeding flycatchers within 15 sites. We also completed surveys for Yellow-billed Cuckoos at these study areas. No cuckoos were detected during surveys or incidentally.

We used targeted mist-net and passive netting techniques to capture and uniquely color-band adult and fledgling willow flycatchers at all sites where resident willow flycatchers were detected. Nestlings were banded between 8 and 10 days of age. We banded each willow flycatcher with a single, numbered U.S. federal aluminum band on one leg and one pin-striped, aluminum band on the other. We used binoculars to determine the identity of previously color-banded flycatchers by observing, from a distance, the unique color combinations on their legs.

At Reclamation study areas, we color-banded 15 new adult flycatchers and recaptured 11 individuals detected in previous years as adults. An additional 31 adults were identified to individual via resighting, while 3 individuals were resighted but did not have their color combinations confirmed. We detected two individuals identified as returning nestlings by the presence of a single federal band, with one (50%) identified to individual via recapture. Two additional returning nestlings with full combinations were recaptured. Thirty adult flycatchers remained unbanded, and banding status was undetermined (i.e., we were unable to determine if these individuals were banded) for 30 adults. We banded 40 nestlings from 17 nests. Of the 40 nestlings banded, 5 were known or suspected to have died before fledging. We banded flycatchers opportunistically at St. George, Utah, capturing and color-banding two new adults and one nestling.

At NDOW study areas, we color-banded 13 new adult flycatchers and recaptured 3 individuals detected in previous years as adults. An additional 25 adults were identified to individual via resighting, while 2 individuals were resighted but did not have their color combinations confirmed. We recaptured one individual identified as a returning nestling by the presence of a single federal band. Three additional adults were captured with a full color combination and identified as returning nestlings from 2009 or 2010. Five adult flycatchers remained unbanded, and banding status was undetermined for one adult. We banded 34 nestlings from 13 nests. Of the 34 nestlings banded, 3 were suspected to have died before fledging.

Of the 96 resident, adult willow flycatchers identified to individual at monitored study areas in 2010, 55 (57%) were identified in 2011; 5 (9%) were detected at a different study area from where they were last detected in 2010. We detected seven within-year, between-study area movements in 2011.

Of the 51 juveniles banded and not known or suspected to have died at Reclamation study areas in 2010, 2 (4%) were identified in 2011. An additional 36 juveniles were banded at NDOW study areas and not known or suspected to have died in 2010; nine (25%) were identified in 2011. Sixteen individuals originally banded as nestlings in previous years were identified for the first time in 2011. Of the 16 returning nestlings identified in 2011, 12 (75%) dispersed away from their natal study area. The median dispersal distance for all returning juvenile flycatchers in 2011 was 12.8 km.

We recorded 50 territories at all Reclamation study areas. Of these, 36 (72%) consisted of paired flycatchers and 14 (28%) consisted of unpaired individuals. Eight breeding males were polygynous, two pairing with three females and six pairing with two females. One female mated consecutively with two different males. One male moved and established a second territory within the same study area. We recorded 24 territories at NDOW study areas. Of these, 21 (88%) consisted of breeding individuals, 1 (4%) consisted of paired individuals with no documented breeding activity, and 2 (8%) consisted of unpaired males. Three males were polygynous; each mated with two females.

At Reclamation study areas, we documented 49 willow flycatcher nesting attempts, 43 of which contained eggs and were used in calculating nest success and productivity. Eighteen (42%) nests were successful and fledged young; and 25 (58%) failed. Mayfield survival probability ranged from 0.198 to 1.000, and was 0.467 for all sites combined (except Topock Marsh where Mayfield nest success could not be calculated due to a lack of data). Depredation was the major cause of nest failure, accounting for 52% of all failed nests and 65% of nests that failed after flycatcher eggs were laid.

We documented 38 flycatcher nesting attempts at NDOW study areas; 36 of these were known to contain flycatcher eggs and were used in calculating nest success and productivity. Of nests known to contain flycatcher eggs, fourteen (39%) were successful and fledged young, and 22 (61%) failed. Depredation accounted for the majority (59%) of all nest failures. Mayfield survival probability was 0.447 at Key Pittman and could not be calculated at River Ranch or Warm Springs due to lack of data.

At Reclamation study areas, 7 of 37 nests (19%) with flycatcher eggs and known contents were brood parasitized by Brown-headed Cowbirds. Brood parasitism at Reclamation study areas ranged from 0 to 60% and was highest at Muddy River. At NDOW study areas, 4 of 34 nests (12%) with flycatcher eggs and known contents were brood parasitized. Brood parasitism was 11% at Key Pittman, 75% at River Ranch, and 0% at Warm Springs. We addled cowbird eggs via vigorous shaking at all easily accessible flycatcher nests. Egg addling appeared to reduce the hatch rate of cowbird eggs, though small sample size precluded rigorous comparisons. Nests that contained flycatcher eggs and were brood parasitized were less likely to fledge flycatcher young than nests that were not parasitized. This is not necessarily due to the success or failure of the addling program as parasitized nests often failed for other reasons (e.g., depredation or failure of flycatcher eggs to hatch).

At Bill Williams River NWR, we gathered data on microclimate characteristics at one location each for two of the territorial male flycatchers we identified; both males obtained mates and had nesting attempts. We also gathered data on vegetation characteristics at these two territories, plus an additional two territories; one of the additional territories was occupied by a nesting pair and the other by an unpaired male. We delineated the following habitat types: 1) Goodding willow with tamarisk understory, and 2) cottonwood/willow. Both of these vegetation types fall within the definition of cottonwood-willow habitat (cottonwoods and willows constituting at least 10% of total trees) as used in the LCR MSCP. We present results for each of our delineated habitat types as well as for the cottonwood-willow vegetation types used in the LCR MSCP. Sample sizes in 2011 are too small to provide an accurate

representation of the range and variance in vegetation and microclimate characteristics in each habitat type.

Both vegetation types (Goodding willow with tamarisk understory and cottonwood/willow) exhibited moist or inundated soil conditions at some point in the breeding season. Daily maximum temperatures spanned a range of ~5°C among habitat types, while daily minimum temperatures spanned <3°C. Vapor pressure increased through the end of July for both habitat types and was higher in Gooding willow with tamarisk understory than in cottonwood/willow.

In 2005, we selected 11 sites between Parker and Imperial Dams for inclusion in the habitat monitoring study addressing how changes in water transfer actions might affect riparian habitat. We also selected two control sites above Parker Dam and two below Imperial Dam. At each site we installed 3–5 temperature/humidity data loggers. Soil moisture measurements were collected at each data logger location in 2011 during each flycatcher survey at the site and when logger data were downloaded. Vegetation measurements were also collected at each data logger location after surveys were completed.

Comparisons of microclimate characteristics among years in 2005–2011 at the habitat monitoring sites indicated hotter and more humid conditions in 2006 and cooler conditions in 2009 than in the other years. The interannual changes in temperature were similar between test and control sites, suggesting that these changes were regional, rather than being influenced by local conditions. The interannual changes in soil moisture in 2005–2006, 2007–2008, and 2009–2010 were not similar between test and control sites, with soil moisture declining more sharply at the control sites during the first two periods and then rising sharply during the third. This suggests that local conditions, in addition to regional climate, may have influenced soil moisture. Although vapor pressure fluctuated more sharply between years at test versus control sites, both test and control sites exhibited fluctuations in vapor pressure that were consistent with the annual fluctuations in dew point recorded at the Needles, California weather station. Thus, regional weather appears to have an overriding influence on humidity within both test and control sites.

We noted between-year differences at the habitat monitoring sites for several vegetation variables, but none of the variables exhibited a unidirectional change across time. Many vegetation characteristics that varied over time showed parallel changes at control and test sites, suggesting either widespread yearly variation or observer variation between years. Few variables showed changes that were specific to control or test sites, and several of those variables had marginally significant (> 0.01) *P*-values. Only woody ground cover and dead vertical foliage had *P*-values < 0.01. Ground cover did not differ from 2005 to 2007 at test locations but increased at control plots in 2006 and then decreased in 2007. It is not clear whether this represents actual changes in the amount of woody ground cover or whether it is a result of observer variation. Vertical foliage counts of dead vegetation have increased overall over the last several years at test plots, although there has been considerable yearly fluctuation, and the percentage of the vertical foliage that consists of live vegetation has dropped accordingly. The interannual fluctuations make it difficult to draw inferences about general trends in vegetation health. In addition, we have not recorded an increase in the number of dead stems, suggesting that there has been no noticeable increase in plant mortality.

It has become apparent, after measuring the same vegetation plots for several consecutive years, that stem counts in very dense vegetation are inherently inaccurate and imprecise and can vary widely from year to year when there has likely been no appreciable change in stem density. Given the difficulties in producing repeatable stem counts, absolute stem counts are likely not a suitable metric for detecting subtle changes in vegetation. The proportion of live stems may provide a more sensitive metric by which to detect change; the accuracy of this measure depends only on each observer counting live stems in a manner consistent with how s/he counts dead stems. Similarly, the proportion of live vertical foliage is likely to provide a more sensitive measure of changes in vegetation than do the absolute vertical foliage counts.

The detection of changes in vegetation as the result of the diversion of water at Parker rather than Imperial Dam is further hampered by the complete lack of vegetation measurements prior to the beginning of the diversion in 2002. Vegetation measurements did not commence until 2005, by which time it is possible that some changes in vegetation, particularly in sensitive species such as coyote willow, had already occurred.

Supplemental water delivery to support habitat enhancement commenced at Topock Marsh in 2011, periodically flooding portions of In Between and 800M. The flooded area at those two sites was the only area surveyed for flycatchers within Topock Marsh that contained surface water during the 2011 breeding season. Water delivery did not appear to have any effects on vegetation that would influence flycatcher occupancy. Water delivery had the expected effect of raising soil moisture, decreasing distance to water, and increasing the percentage of the area surrounding each sample point that was inundated or saturated. Water delivery also increased humidity within the flooded area. Flood events produced a lower maximum temperature, higher minimum temperature, and smaller daily temperature range in the flooded area in comparison to the non-flooded area, but these effects did not seem to persist across two-week periods. Areas occupied by flycatchers typically have higher soil moisture, higher humidity, and more moderate temperatures than unoccupied areas; thus, water delivery appeared to change the conditions within the flooded area in ways that would favor flycatcher occupancy. Water delivery was the most effective at creating conditions favored by flycatchers when the underlying water table was high. Despite the presence of favorable conditions, flycatcher occupancy in the target area did not increase in 2011, possibly because dry conditions elsewhere in Topock Marsh and a low flycatcher population may have limited the ability of flycatchers to colonize the area.

Chapter 1

INTRODUCTION

PROJECT HISTORY

In 1995, the U.S. Bureau of Reclamation (Reclamation), other federal, state, and tribal agencies, and environmental and recreational interests agreed to form a partnership to develop and implement a Multi-Species Conservation Program (MSCP) for long-term endangered species compliance and management in the historical floodplain of the lower Colorado River (LCR). As a step to developing the LCR MSCP, Reclamation prepared a Biological Assessment (BA) in August 1996, evaluating the effects of dam operations and maintenance activities on threatened, endangered, and sensitive (TES) species. These species included the Southwestern Willow Flycatcher (*Empidonax traillii extimus*), which was listed by the U.S. Fish and Wildlife Service (USFWS) as endangered in 1995 (60 FR 10694–10715). In response to the BA, the USFWS issued a Biological Opinion (BO) in April 1997 outlining several terms and conditions Reclamation must implement in order not to jeopardize the species. Among these terms and conditions was the requirement to survey and monitor occupied and potential habitat for Southwestern Willow Flycatchers along the LCR for a period of five years. The studies were intended to determine the number of willow flycatcher territories, status of breeding pairs, flycatcher nest success, the biotic and abiotic characteristics of occupied willow flycatcher sites, and Brown-headed Cowbird (*Molothrus ater*) brood parasitism rates. In 2002, Reclamation reinitiated consultation with USFWS on the effects of continued dam operations and maintenance on TES species along the LCR. The USFWS responded with a BO in April 2002 requiring continued Southwestern Willow Flycatcher studies along the LCR through April 2005. The BO also required implementation of a study to evaluate the effectiveness of Brown-headed Cowbird trapping for conservation of the flycatcher.

Reclamation and USFWS completed a separate consultation on the potential effects to threatened and endangered species from implementation of surplus guidelines through 2016 and an annual change in the point of diversion for up to 400,000 acre-feet for 75 years. A Biological Opinion for Interim Surplus Criteria, Secretarial Implementation Agreements, and Conservation Measures was issued in January 2001 and required monitoring of 150.5 ha of existing, occupied Southwestern Willow Flycatcher habitat between Parker and Imperial Dams.

The LCR MSCP is a 50-year program that seeks to protect 26 TES species and their habitats along the LCR while maintaining river regulation and water management required by law. The LCR MSCP was approved in April 2005 with the signing of a Record of Decision by the Secretary of the Department of the Interior, and implementation of the program began in October 2005. Documentation for the LCR MSCP includes a Habitat Conservation Plan (HCP), BA/BO, and an Environmental Impact Statement. The HCP specifies monitoring and research measures that call for surveys and research to better define habitat requirements for the Southwestern Willow Flycatcher and studies to determine the effects of cowbird nest parasitism on flycatcher reproduction.

Reclamation initiated willow flycatcher studies along the LCR in 1996, in anticipation of the requirements outlined in the BOs that were part of LCR MSCP development. These studies have been conducted annually since 1996. From 1997 to 2010,[1] breeding populations of Southwestern Willow Flycatchers were documented at eight study areas along the Virgin and lower Colorado Rivers and tributaries: (1) Pahranagat National Wildlife Refuge (NWR), Nevada; (2) Beaver Dam Wash at Littlefield, Arizona; (3) Mesquite and (4) Mormon Mesa on the Virgin River, Nevada; (5) Overton

[1] Studies in 1996 did not include any sites in Nevada.

Wildlife Management Area (WMA) along the Muddy River, Nevada; (6) Grand Canyon, Arizona; (7) Topock Marsh on the Colorado River, Havasu NWR, Arizona; and (8) Bill Williams River NWR (Bill Williams), Arizona (McLeod et al. 2008a; McLeod and Koronkiewicz 2009, 2010; McLeod and Pellegrini 2011; Braden and McKernan unpubl. data). From 1997 to 2010, willow flycatchers, including one banded migrant Southwestern Willow Flycatcher (Koronkiewicz et al. 2006a), were detected during the breeding season at several sites along the Colorado River south of the Bill Williams River to the Mexico border, but no nesting activity was confirmed.

In compliance with the consultation on Interim Surplus Criteria and Secretarial Implementation Agreements, Reclamation biologists deployed temperature/humidity data loggers in 2004 at a subset of sites currently monitored for Southwestern Willow Flycatcher along the Colorado River in California and Arizona. These studies were expanded in 2005 to include annual monitoring of groundwater levels, vegetation, and soil moisture in addition to temperature and humidity.

Following the breeding season of 2008, USFWS and Reclamation initiated discussions regarding the declining number of willow flycatcher territories at Topock Marsh in 2004–2008, the importance of the flycatcher population in the Topock area to flycatcher conservation along the LCR, and possible measures to enhance flycatcher habitat at Topock. A plan was developed to pump water into a portion of the flycatcher breeding habitat at Topock beginning in February or March and continuing into the flycatcher breeding season. The selected area at Topock had seen the greatest decline in numbers of resident flycatchers but had not experienced any dramatic changes in vegetation. Water delivery was anticipated to commence in 2010, and monitoring of vegetation, microclimate, and hydrologic condition in the target area was initiated in 2009 to obtain baseline conditions in the target area. Water delivery was delayed until 2011, so additional monitoring of baseline conditions occurred in 2010.

RELATED STUDIES

Prior to 2010, Nevada Department of Wildlife (NDOW) completed nest monitoring at Key Pittman WMA, and SWCA Environmental Consultants (SWCA) banded flycatcher nestlings and adults opportunistically in cooperation with the monitoring efforts. In 2010, NDOW retained SWCA to conduct surveys, site descriptions, nest monitoring, and banding at flycatcher breeding areas at Key Pittman WMA and Warm Springs Natural Area. This work was expanded in 2011 to include River Ranch in the Pahranagat Valley. SWCA also completed surveys for Yellow-billed Cuckoo (*Coccyzus americanus occidentalis*) at Key Pittman and River Ranch. Results of surveys, site descriptions, nest monitoring, and banding efforts at Key Pittman, River Ranch, and Warm Springs are presented in Chapters 2, 3, and 4.

Utah Division of Wildlife Resources monitored breeding flycatchers in St. George, Utah. SWCA banded adults and nestlings opportunistically in St. George in cooperation with the monitoring efforts. Banding results from St. George are presented in a separate table in Chapter 3.

SPECIES INTRODUCTION

The Southwestern Willow Flycatcher is one of four subspecies of willow flycatcher currently recognized (Unitt 1987), although Browning (1993) posits a fifth subspecies (*E. t. campestris*) occurring in the central portions of the United States (Figure 1.1). The Southwestern Willow Flycatcher breeds in dense, mesic riparian habitats at scattered, isolated sites in New Mexico, Arizona, southern California, southern Nevada, southern Utah, southwestern Colorado, and, at least historically, extreme northwestern Mexico and western Texas (Unitt 1987).

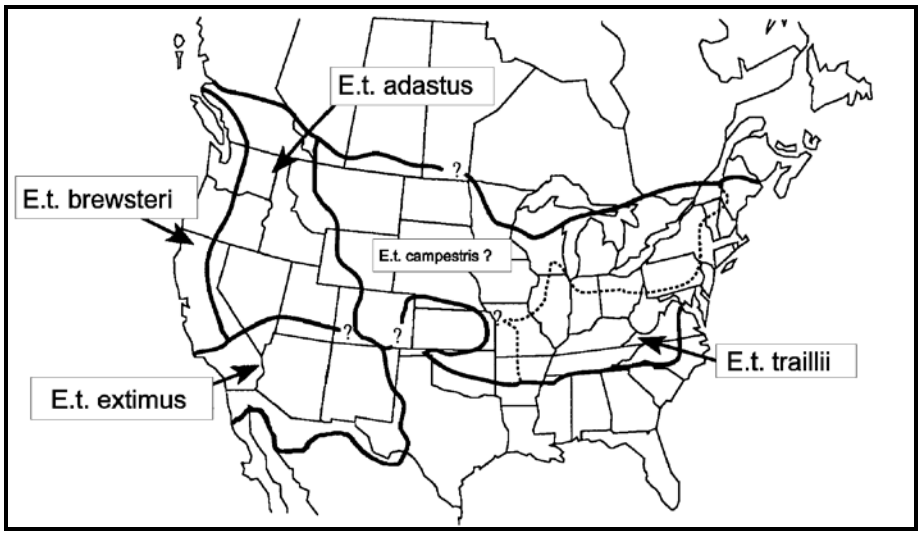

Figure 1.1. Breeding range distribution of the subspecies of the willow flycatcher (*Empidonax traillii*). Adapted from Unitt (1987), Browning (1993), and Sogge et al. (1997).

In the Southwest, most willow flycatcher breeding territories are found within small breeding sites containing five or fewer territories (Durst et al. 2006). One of the last long-distance Neotropical migrants to arrive in North America in spring, Southwestern Willow Flycatchers have a short, approximately 100-day breeding season, with individuals typically arriving in May or June and departing in August (Sogge et al. 1997). All four subspecies of willow flycatchers spend the non-breeding season in portions of southern Mexico, Central America, and northwestern South America (Stiles and Skutch 1989, Ridgely and Tudor 1994, Howell and Webb 1995, Unitt 1997), with wintering ground habitat similar to the breeding grounds (Lynn et al. 2003). Willow flycatchers have been recorded on the wintering grounds from central Mexico to southern Central America as early as mid-August (Stiles and Skutch 1989, Howell and Webb 1995), and wintering, resident individuals have been recorded in southern Central America as late as the end of May (Koronkiewicz et al. 2006b).

Historical breeding records and museum collections indicate that a sizable population of Southwestern Willow Flycatchers may have existed along the extreme southern stretches of the LCR region (Unitt 1987). However, no nests have been located south of the Bill Williams River, Arizona, in over 65 years (Unitt 1987), though northbound and southbound migrant willow flycatchers use the riparian corridor (Phillips et al. 1964; Brown et al. 1987; McKernan and Braden 2002; McLeod et al. 2008a; McLeod and Koronkiewicz 2009, 2010; McLeod and Pellegrini 2011; this document). Factors contributing to the decline of flycatchers on the breeding grounds include loss, degradation, and/or fragmentation of riparian habitat; invasion of riparian habitat by nonnative plants; and brood parasitism by Brown-headed Cowbirds (USFWS 1995, Marshall and Stoleson 2000). Because of low population numbers range-wide, identifying and conserving willow flycatcher breeding sites is thought to be crucial to the recovery of the species (USFWS 2002).

Tamarisk beetles (*Diorhabda* spp.) may pose an additional threat to Southwestern Willow Flycatchers. Tamarisk beetles defoliate tamarisk (*Tamarix* spp.) plants during flycatcher breeding season, likely exposing flycatcher nests to adverse microclimate conditions and increased risk of depredation and parasitism. Tamarisk beetles were released in St. George, Utah, in 2006, and widespread defoliation was first observed in St. George in 2008. The area of defoliation on the Virgin River has expanded downstream annually since then, encompassing Littlefield, Arizona, in 2009; the Highway 170 bridge

downstream of Bunkerville, Nevada, in 2010; and the entire stretch of the Virgin River to Lake Mead by the end of the breeding season in 2011.

PURPOSE AND DESCRIPTION OF STUDY

The purpose of the 2011 study is to continue surveys, monitoring, and demographic and ecological studies of the Southwestern Willow Flycatcher in suitable and/or historical riparian and wetland habitats throughout the lower Colorado and Virgin River region. Lower Grand Canyon was not visited in 2009–2011 because the declining level of Lake Mead dramatically reduced the amount of potential flycatcher habitat, and the formation of rapids at Pearce Ferry and Iceberg Canyon made access difficult and dangerous. This project encompasses four types of studies: (1) presence/absence surveys, including site descriptions, at preselected sites along the lower Colorado River and portions of major tributaries; (2) intensive studies at all study areas where breeding flycatchers are located to assess Southwestern Willow Flycatcher demographics and ecology, habitat selection, and the effects of Brown-headed Cowbird brood parasitism; (3) monitoring of microclimate, vegetation, and groundwater conditions of currently occupied[2] Southwestern Willow Flycatcher habitat between Parker and Imperial Dams; and (4) monitoring microclimate, vegetation, and surface hydrology in a selected portion of flycatcher habitat within Topock Marsh to document the effects of habitat enhancement efforts. SWCA's contract specifies the following field tasks:

Presence/absence Surveys. At approximately 100 sites along the LCR, conduct presence/absence surveys, following a 5-survey protocol (per USFWS 2000).

Site Descriptions. Provide a general site description for each site, including major types of vegetation and hydrological conditions, at least three times during the survey period.

Nest Monitoring. Search for nests in all areas occupied by territorial flycatchers, and monitor all nests to determine nest fate, brood parasitism, and causes of nest failure.

Banding. Band as many adult and juvenile flycatchers as possible at sites with territorial flycatchers.

Vegetation, Soils, and Microclimate. Collect vegetation, soil, and microclimate data at the within-territory level at breeding locations in order to quantify conditions at flycatcher territories for replication at restoration areas.

Habitat Monitoring. At 15 previously identified sites, monitor vegetation, microclimate, and groundwater conditions to determine how these may be affected by water transfer actions at Parker Dam.

Surface Hydrology, Vegetation, and Microclimate Monitoring. Within a selected portion of Topock Marsh, monitor surface hydrology, microclimate, and vegetation conditions.

Each distinct aspect of the 2011 study is addressed in a separate chapter in this report, as follows:

Chapter 2 – Presence/absence Surveys and Site Descriptions. This chapter presents the methodology and results for presence/absence surveys and gives a general site description for each survey site.

[2] As per Reclamation (1999), we defined occupied Southwestern Willow Flycatcher habitat as patches of vegetation that are similar to and contiguous with areas where willow flycatchers were detected after 15 June in any year, 1996–2011.

Chapter 3 – Color-banding and Resighting. Details of banding activities and resighting of previously banded flycatchers are presented in this chapter. Also included are discussions of within- and between-year movement of individual flycatchers.

Chapter 4 – Nest Monitoring. This chapter summarizes nesting attempts, nest fates, and productivity for all Southwestern Willow Flycatcher nesting activity.

Chapter 5 – Vegetation and Habitat Characteristics. Vegetation sampling methods are described, and vegetation characteristics are summarized for territories in different habitat types.

Chapter 6 – Microclimate. The methodology of monitoring temperature, humidity, and soil moisture is described, and microclimate characteristics are summarized for flycatcher territories in different habitat types.

Chapter 7 – Habitat Monitoring: Parker to Imperial Dams. The methodology and results of monitoring microclimate, vegetation, and groundwater conditions at occupied sites between Parker and Imperial Dams are presented.

Chapter 8 – Surface Hydrology, Microclimate, and Vegetation Monitoring: Topock Marsh. This chapter describes sampling methods and compares baseline conditions documented in 2009 and 2010 to those documented in 2011 in an area targeted for habitat enhancement.

Chapter 9 – Management and Study Design Recommendations. Recommendations from all previous report chapters are summarized for ease of reference.

Chapter 2

PRESENCE/ABSENCE SURVEYS AND SITE DESCRIPTIONS

INTRODUCTION

Broadcasts of recorded conspecific vocalizations are useful in eliciting responses from nearby willow flycatchers, and multiple broadcast surveys conducted throughout the breeding season are the standard technique for determining the presence or absence of *E. t. extimus* (Sogge et al. 2010). According to Sogge et al. (2010) and USFWS (2002), willow flycatchers detected between approximately 15 June and 20 July in the breeding range of *E. t. extimus* probably belong to the southwestern subspecies. However, because northbound individuals of all western subspecies of the willow flycatcher migrate through areas where *E. t. extimus* are actively nesting, and southbound migrants occur where *E. t. extimus* are still breeding (Sogge et al. 2010, USFWS 2002), field confirmation of the southwestern subspecies is problematic.[1] For example, the northwestern *E. t. brewsteri*, far more numerous than *E. t. extimus*, has been documented migrating north in southern California as late as 20 June (Garrett and Dunn 1981 as cited in Unitt 1987), and Phillips et al. (1964 as cited in Unitt 1987) documented *E. t. brewsteri* collected in southern Arizona on 23 June. An understanding of willow flycatcher migration ecology in combination with multiple broadcast surveys conducted throughout the breeding season is therefore needed to assess the presence and residency of Southwestern Willow Flycatchers.

Migration routes used by *E. t. extimus* are not well documented, though more is known of northbound migration in spring than the southbound migration in fall because flycatchers are more vocal in spring and can therefore be distinguished from other *Empidonax* species. During northbound migration, all subspecies of willow flycatchers use riparian habitats similar to breeding habitat along major river drainages in the Southwest such as the Rio Grande (Finch and Kelly 1999), Colorado River (McKernan and Braden 1999), San Juan River (Johnson and Sogge 1997), and the Green River (M. Johnson unpubl. data). Although migrating willow flycatchers may favor young, native willow habitats (Yong and Finch 1997), migrants are also found in both spring and fall in a variety of habitats that are unsuitable for breeding. These migration stopover habitats, even though not used for breeding, are likely important for both reproduction and survival. For most long-distance Neotropical migrant passerines, migration stopover habitats are needed to replenish energy reserves to continue northbound or southbound migration.

In 2011, as part of our contract with Reclamation, we completed multiple broadcast surveys at sites in 11 study areas[2] (hereafter Reclamation study areas) along the LCR and its tributaries to detect both migrant and resident willow flycatchers (Figure 2.1). We also completed surveys in three additional study areas (Key Pittman, River Ranch, and Warm Springs; hereafter NDOW study areas) as part of our contract with NDOW.

Special Concern Species

The Yuma Clapper Rail (*Rallus longirostris yumanensis*) is listed as federally endangered by the USFWS, and the Yellow-billed Cuckoo is a candidate for federal listing. Both species occur along the LCR and its tributaries and are of concern to managing agencies. Nine additional avian species [California Black Rail (*Laterallus jamaicensis coturniculus*), Least Bittern (*Ixobrychus exilis*), Elf Owl (*Micrathene whitneyi*),

[1] Throughout this document, the terms "flycatcher" and "willow flycatcher" refer to *E. t. extimus* when individuals are confirmed as residents. For individuals for which residency is undetermined, subspecies is unknown.

[2] Study areas consist of 1–18 survey sites that are grouped geographically (see Table 2.2).

Figure 2.1. Locations of Southwestern Willow Flycatcher study areas along the lower Colorado River and tributaries, 2011. (Note, study area labels represent the approximate center of multiple sites within that region; see Table 2.2)

Gila Woodpecker (*Melanerpes uropygialis*), Gilded Flicker (*Colaptes auratus chrysoides*), Vermilion Flycatcher (*Pyrocephalus rubinus*), Arizona Bell's Vireo (*Vireo bellii arizonae*), Sonoran Yellow Warbler (*Setophaga petechia sonorana*), and Summer Tanager (*Piranga rubra*)] are considered to be special-concern species under the LCR MSCP. The Yellow-breasted Chat (*Icteria virens*) is also considered a special concern species in California. We did not survey specifically for these species at the 11 Reclamation study areas but recorded all incidental detections. We recorded all incidental detections of special concern species at all three NDOW study areas and completed surveys for Yellow-billed Cuckoos at Key Pittman and River Ranch.

METHODS

Site Selection

Survey sites were selected based on locations surveyed during previous years of willow flycatcher studies on the LCR (McKernan 1997; McKernan and Braden 1998, 1999, 2001a, 2001b, 2002; McLeod et al. 2008a; McLeod and Koronkiewicz 2009, 2010; McLeod and Pellegrini 2011) and reconnaissance on foot prior to the start of the 2011 survey period. Sites consisting of mature native or exotic woody riparian vegetation with high canopy closure (>50%) and standing water or saturated soil under or adjacent to the vegetation were considered the most suitable habitats for flycatchers. Early successional stands of young riparian vegetation >3 m in height in proximity to surface water or saturated soil were also considered potentially suitable flycatcher habitat. Riparian vegetation contiguous with suitable habitat was often included as part of survey areas. Reclamation biologist Chris Dodge guided and approved site selection at the 11 Reclamation study areas. For sites surveyed in previous years, we retained original site names.

In 2008 we implemented a biennial survey schedule at selected sites in study areas where resident flycatchers had not been documented in the previous 10 years of surveys. Sites were selected for biennial surveys based on the absence of damp or wet soils within the site and/or the relative absence of dense vegetation that might provide suitable nesting habitat for flycatchers. After the 2008 survey season, we revised the survey schedule based on conditions observed in the field and added several sites at Bill Williams to the biennial schedule. These sites were ones at which no resident flycatchers had been detected since 2003. The proposed schedule at the beginning of the 2011 survey season is given in Table 2.1 and may be further revised based on conditions observed during 2011.

Table 2.1. Proposed Survey Schedule for Selected Sites

Study Area[1]	Site	Habitat Comments	Proposed Survey Schedule		
			Annual	2008, 2010, 2012	2009, 2011
TOGO[2]	Pulpit Rock	Tiny. Wet soil adjacent to river; upland edge dry.			X
	Picture Rock	Wet soil adjacent to river; interior dry.			X
	Blankenship Bend North	Stand of willow adjacent to marsh.	X		
	Blankenship Bend South	Mosaic of cattail, bulrush, willow. Areas with water under vegetation.	X		
	Havasu NE	Mature vegetation; interior of site is completely dry, no water beneath the vegetation.		X	

Table 2.1. Proposed Survey Schedule for Selected Sites (Continued)

Study Area[1]	Site	Habitat Comments	Proposed Survey Schedule		
			Annual	2008, 2010, 2012	2009, 2011
BIWI	Site #1	Mixed-native vegetation; dry soils and stands of dense arrowweed in the center of the site; coyote willow and surface water along the site edge, bordering an arm of Lake Havasu.		X	
	Site #2	Mature mixed-native vegetation; dry soils and extensive deadfall within the site; bordered by an arm of Lake Havasu.		X	
	Site #11	Mature mixed-native vegetation; dry soils and extensive deadfall within the site; bordered by an arm of Lake Havasu.		X	
	Black Rail	Mixed-native vegetation; generally sparse understory; narrow strip of dense vegetation.		X	
	Mineral Wash	Mixed-native vegetation; sparse canopy closure; dry soil underneath the vegetation; water only within river channels.		X	
	Beaver Pond	Mixed-native vegetation; sparse canopy closure; dry soil underneath the vegetation; water only within river channels.		X	
	Site #8	Mixed-native vegetation; sparse canopy closure; dry soil underneath the vegetation; water only within the river channel.		X	
PVER	PVER Phase 2	Restoration area.	X		
	PVER Phase 3	Restoration area.	X		
EHRE	Ehrenberg	Emergent cottonwood and Goodding willow; understory primarily arrowweed and *Baccharis* sp.; formerly contained a dense stand of coyote willow but these willows have all died.		X	
CIBO	CVCA Phase 1	Restoration area.	X		
	CVCA Phase 2	Restoration area.	X		
	CVCA Phase 3	Restoration area.	X		
	Cibola Nature Trail	Generally dry and sparse. Restoration area; habitat improvements taking place, may improve.	X		
	Cibola Island	Narrow, linear site; patches of dense Goodding willow adjacent to marsh.	X		
	Cibola Site 2	No dense canopy. Mostly tamarisk with some emergent willow. Cattail marshes in parts of the site, but dry soil under the tamarisk.			X
	Cibola Site 1	No dense canopy. Mostly tamarisk with some emergent willow. Cattail marshes in parts of the site, but dry soil under the tamarisk.			X
	Three Fingers Lake	Vegetation short, very dry and hot in interior.		X	
	Cibola Lake #1 (North)	Patchy vegetation, hot and dry in interior.		X	
	Cibola Lake #2 (East)	Patchy vegetation, hot and dry in interior.			X
	Cibola Lake #3 (West)	Patchy vegetation, hot and dry in interior.		X	
	Walker Lake	Tamarisk with emergent willows; water under vegetation along lake edge.	X		
IMPE	Paradise	Some big willows with tamarisk understory, sometimes has water in marshes.	X		
	Hoge Ranch	Mosaic of tamarisk, willow, and marshes. Sometimes wet.	X		
	Adobe Lake	Perched above river, very dry; dense tamarisk with many dead branches in understory.		X	
	Rattlesnake	Dense willows, wet soils.	X		

Table 2.1. Proposed Survey Schedule for Selected Sites (Continued)

Study Area[1]	Site	Habitat Comments	Proposed Survey Schedule		
			Annual	2008, 2010, 2012	2009, 2011
IMPE	Milemarker 65	Very narrow strip (<50m) of tamarisk adjacent to bulrush marsh. Understory of *Phragmites* creates extremely dense vegetation within 3 m of ground.			X
	Clear Lake/The Alley	Mature tamarisk, very dense understory. Very dry except immediately next to backwater channel.		X	
	Nursery NW	Dense tamarisk interspersed with marsh areas.	X		
	Imperial Nursery	Plantation. No understory.		X	
	Ferguson Lake	Mix of willow and tamarisk with water under vegetation on west side of site. East side dry and scrubby.	X		
	Ferguson Wash	Mature tamarisk with emergent willow. Very dry in interior of site. Borders backwater channel and Ferguson Lake. Moist soils only along channel edge.		X	
	Great Blue Heron	Goodding willow overstory, tamarisk understory; moist soils in parts of the site.	X		
	Powerline	Very small. Stringer of trees around cattail marsh that sometimes contains water. Sparse canopy.			X
	Martinez Lake	Scattered willows, tamarisk and arrowweed understory, sparse canopy closure.			X
MITT	Mittry West	Willow overstory, tamarisk understory, 80% canopy closure; sometimes wet.	X		
	Mittry South	Monotypic tamarisk, lots of deadfall. Interior dry. Adjacent to lake.		X	
YUMA	Gila Confluence North	Patchy. A few small stands of mature willows around cattail marshes. Marshes sometimes contain water. Half of site burned in 2006. Overall canopy closure 50%.		X	
	Gila River Site #2	Cottonwood/willow overstory, tamarisk and arrowweed understory; dry soils in interior; canopy closure 50%.			X
	Fortuna Site #1	Narrow (30m) strip of cottonwood/willow. Patchy understory of tamarisk and arrowweed on periphery, no understory within cottonwood/willow. Interior dry.			X
	Fortuna North	Mature tamarisk, 80% canopy closure. Interior very dry. Adjacent to Gila River.			X

[1] TOGO = Topock Gorge, BIWI = Bill Williams River NWR, PVER = Palo Verde Ecological Reserve, EHRE = Ehrenberg, CIBO = Cibola, IMPE = Imperial, MITT = Mittry Lake, YUMA = Yuma.

[2] No surveys were completed in Topock Gorge in 2011 because effort was redirected to hydrology monitoring at Topock Marsh (see Chapter 8).

We provided field personnel with high-resolution aerial photographs of all selected survey sites. The photographs were overlain with a UTM grid (NAD 83) and an outline of the proposed survey area. The boundaries of all survey sites were refined to include potential flycatcher habitat actually present. New boundaries were delineated on the aerial photographs based on UTM coordinates obtained in the field. All UTM coordinates were obtained using a Garmin Rino 110 GPS unit and were in NAD 83 to comply with Federal Geographic Data Committee standards.

Additional Site Evaluation

During the survey season, we conducted on-the-ground habitat reconnaissance and evaluation to locate additional potentially suitable willow flycatcher habitat and to reevaluate areas we had visited in previous years and had noted as having the potential to become suitable habitat. Field personnel were provided high-resolution aerial photographs overlain with a UTM grid to aide with navigation and the identification of potentially suitable flycatcher habitat. We focused habitat reconnaissance and evaluation in areas that contained or were adjacent to standing water or saturated soils, and that had vegetation characteristics similar to that of flycatcher breeding sites (i.e., dense vegetation within 2–4 m of the ground and high canopy closure). Broadcast surveys were conducted opportunistically during ground reconnaissance. Field personnel formulated qualitative site descriptions of all evaluated areas.

Broadcast Surveys

To elicit responses from nearby willow flycatchers, we broadcast conspecific vocalizations previously recorded throughout the Southwest from 1996 to 1998. All flycatcher surveys were conducted according to methods described in Sogge et al. (2010), and we followed a 5-survey protocol, as recommended by the U.S. Fish and Wildlife Service (USFWS 2000). We completed at least one survey between 15 and 31 May, at least one survey between 1 and 15 June, and three additional surveys between 16 June and 25 July. Surveys were separated by a minimum of five days whenever logistically possible. Field personnel surveyed within the habitat wherever possible, using a Sansa® ClipMP3 player coupled to a Radio Shack 277-1008C mini amplified speaker. Surveyors stopped every 30–40 m and broadcast willow flycatcher primary song (*fitz-bew*) and calls (*breets*). Field personnel watched for flycatchers and listened for vocal responses for approximately one to two minutes before proceeding to the next survey station. Wherever territorial flycatchers were detected, we discontinued broadcast surveys within a radius of 50 m of territories and commenced territory and nest monitoring, which involves more frequent visits (see Chapter 4). If an unidentified *Empidonax* flycatcher was observed but did not respond with song to the initial broadcast, we broadcast other conspecific vocalizations including *creets/breets*, *wee-oos*, *whitts*, *churr/kitters*, and a set of interaction calls given by a mated pair of flycatchers (per Lynn et al. 2003). These calls are frequently effective in eliciting a *fitz-bew* song, thereby enabling surveyors to positively identify willow flycatchers. To produce a spatial representation of all survey areas, field personnel recorded survey start and stop UTM coordinates as well as the UTM coordinates of intermediate survey points. Observers recorded start and stop times and the location(s) and behavior of all willow flycatchers detected (see survey form, Appendix A). Field personnel also recorded the presence of Brown-headed Cowbirds (hereafter cowbirds) and livestock, as requested by the Arizona Game and Fish Department. Cowbirds may affect flycatcher populations by decreasing flycatcher productivity (see Chapter 4), while livestock may substantially alter the vegetation in an area (USFWS 2002).

Site Description

Because vegetation structure and hydrology within riparian habitats are seasonally dynamic, field personnel completed site description forms (Appendix A) for each survey site at least three times throughout the survey season: early season (mid-May), mid-season (mid-June), and late season (mid-July). Vegetation composition (native vs. exotic) at survey sites followed the definitions of Sogge et al. (2010) and the Southwestern Willow Flycatcher Range-wide Database. Vegetation composition was defined as (1) native: >90% of the vegetation at a site was native; (2) exotic: >90% of the vegetation at a site was exotic/introduced; (3) mixed-native: 50 to 90% of the vegetation at a site was native; or (4) mixed-exotic: 50 to 90% of the vegetation at a site was exotic/introduced. Information from site

description forms was used in conjunction with habitat photographs and comments in field notebooks and on survey forms to formulate qualitative site descriptions.

RESULTS

Reclamation Study Areas

Field personnel spent 469.6 observer-hours conducting willow flycatcher broadcast surveys at 59 sites along the Virgin and lower Colorado Rivers and tributaries.[3] Willow flycatcher survey and monitoring results are summarized in Table 2.2 and are presented below along with site descriptions. Details of occupancy, pairing, color-banding, and breeding are presented in Chapters 3 and 4. The boundaries of survey sites and occupancy in 2011 are shown on orthophotos in Appendix B, along with historically occupied habitat.[4] We did not complete surveys at sites in Topock Gorge because effort was redirected toward hydrology monitoring within Topock (see Chapter 8). Each site that was not occupied by territorial flycatchers was formally surveyed three to six times. A summary of willow flycatcher survey effort and survey site occupancy status is presented in Appendix C. Field personnel spent an additional 24.3 observer-hours completing habitat reconnaissance and evaluation and opportunistic surveys. The results of reconnaissance for each study area are presented below following the results for the regularly surveyed sites. Because subspecies identification of willow flycatchers detected between approximately 15 June and 20 July in the breeding range of *E. t. extimus* is problematic (Sogge et al. 2010, USFWS 2002), flycatcher detections after 15 June at sites where breeding or residency was not confirmed are summarized in Table 2.3. Yellow-billed Cuckoo and Yuma Clapper Rail detections are listed in Tables 2.4 and 2.5, respectively, and overall numbers of detections of all special concern species are listed in Appendix D. Hydrologic characteristics of each site are summarized in Table 2.6.

Table 2.2. Adult Willow Flycatcher Detections at Reclamation Study Areas, 2011*

Study Area[1]	Survey Site	Area (ha)	Number Detected (Date(s) of Detection)[2,3,4,5]
PAHR	North	4.6	14 (15 May–16 Aug), 2 (18 May), 1 (17–19 Jun), 2 (12 Jul), 1 (13 Jul), 1 (4 Aug)
	West	1.5	1 (21 Jul)[6]
MESQ	Hafen Lane	6.1	2 (30 Jun–23 Jul), 1 (21–23 Jul)

MUDD	Overton WMA Pond	0.7	1 (2–5 Jul)
	Overton WMA	14.9	13 (14 May–7 Aug), 1 (6 Jul), 1 (2–3 Aug)

[3] We started the survey season with 57 sites scheduled for surveys in 2011. Two sites were added after reconnaissance revealed potential flycatcher habitat. We discontinued surveys at one site because of poor habitat quality.

[4] As per Reclamation (1999), we defined occupied Southwestern Willow Flycatcher habitat as patches of vegetation that are similar to and contiguous with areas where willow flycatchers were detected after 15 June.

* This table includes only sites where regular surveys were scheduled or where flycatcher were detected and does not include sites where habitat reconnaissance or opportunistic surveys were conducted and no flycatchers were detected.

[1] PAHR = Pahranagat NWR, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR, PVER = Palo Verde Ecological Reserve, CIBO = Cibola, IMPE = Imperial, MITT = Mittry Lake, YUMA = Yuma.

[2] ND = No willow flycatchers were detected.

[3] See Chapter 3 for details on territories, residency, pairing, and color-banding; see Chapter 4 for details on nesting activity.

[4] Flycatchers in territories that were occupied throughout the breeding season are shown as being present throughout the season. Flycatchers detected on a single occasion or for a short period of time are listed separately.

[5] We detected several within-season movements between study areas in 2011. For details on movements see Table 3.9.

[6] Detection was of a banded family group (one adult with fledges) from Pahranagat North.

[7] Surveys discontinued because of poor quality habitat.

[8] This individual detected 7 May–28 Jun in 800M and 6–8 Jul in Pipes #3.

[9] This individual detected 16 May–10 Jun in Platform and 25 Jun–9 Jul in The Wallows.

[10] Not an official survey site. Incidental detections recorded.

[11] Site surveyed at beginning of season for reconnaissance. Not added to formal survey list due to unsuitable habitat.

[12] Site discovered with breeding flycatchers toward end of survey season.

[13] A singing male was reported at this territory by personnel from an unrelated field crew prior to 10 Jul; only the female was detected during nest monitoring visits 10–16 Jul.

* Values are given for each site as recorded in mid-May, mid-June, and mid-July.

[1] PAHR = Pahranagat NWR, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR, PVER = Palo Verde Ecological Reserve, CIBO = Cibola, IMPE = Imperial, MITT = Mittry Lake, YUMA = Yuma.

[2] -- = Hydrologic information not recorded.

[3] Percent of site with saturated soil does not include inundated areas.

[4] Site bordered by a river, lake, or pond.

[5] Saturated soil or water was present only in pig wallows.

[6] Site borders marsh.

[7] Site is irrigated as part of restoration efforts; amount of standing water highly variable throughout survey season.

[8] Site not visited until July; not formally surveyed.

Pahranagat National Wildlife Refuge, Nevada

Pahranagat National Wildlife Refuge consists of a series of lakes and marshes in Pahranagat Valley approximately 150 km north of Las Vegas, Nevada. Patches of primarily native vegetation exist at the inflow and outflow of Upper Pahranagat Lake and along the lakeshore. Prior to the 2008 survey season, the majority of the riparian vegetation along the north side of the upper lake (Pahranagat North) was

inundated annually with up to 1 m of water, with the highest water levels occurring in May. Major structural problems with the dam that impounds the upper lake resulted in the upper lake being drained in early 2008, and the riparian vegetation at the north end of the lake was not flooded during the 2008 or 2009 breeding seasons. The dam was repaired prior to the 2010 breeding season, and lake levels in 2010 and 2011 were higher than they had been in the two previous years but not as high as they had been prior to 2008.

PAHRANAGAT NORTH

Area: 4.6 ha Elevation: 1,026 m

Pahranagat North is a stand of large-diameter Goodding willow (*Salix gooddingii*) at the inflow of Upper Pahranagat Lake. Fremont cottonwood (*Populus fremontii*; hereafter cottonwood) lines the northern, upland edge of the site and extends in narrow stringers around the edge of the lakebed. Canopy height within the patch is around 20 m, and canopy closure is approximately 80%. Many of the large trees in the northeastern section of the site are dead or dying. Additional scattered cottonwood trees have fallen throughout the site creating multiple small clearings. Standing water and saturated soils were present within the southern portion of the site in May, and the site slowly dried out during the survey season, with no water or saturated soils present by the middle of July except in an inflow channel that runs along the northern side of the site and drains into the lakebed at the southeastern corner of the site.

We detected 10 breeding willow flycatchers, as well as 4 resident, unpaired males and 7 individuals for which residency could not be determined. The site lies immediately adjacent to a cattle pasture, and a lack of fencing coupled with low lake levels allowed cattle to periodically access to the site for a portion of the breeding season. We surveyed the unoccupied east arm of the site four times, totaling 1.5 observer-hours.

PAHRANAGAT WEST

Area: 1.5 ha Elevation: 1,026 m

This native site consists of a stringer of cottonwood, one to three trees wide and 20 m in height, on the western edge of Upper Pahranagat Lake. The site has no significant understory vegetation, and canopy closure varies from <50 to 80%. The eastern edge of the site is vegetated with bulrush, which extends into the lakebed to the east. The western edge of the site is vegetated in yerba mansa (*Anemopsis californica*) extending into dry, upland desert. During the survey season, the interior of the site was dry, but surface water was present adjacent to the site in the lakebed.

We detected one adult and one hatch year willow flycatcher on 21 July and two additional hatch year willow flycatchers on 21–25 July; all individuals were known or suspected to have come from Pahranagat North. We surveyed the site five times, totaling 3.1 observer-hours. No cowbirds were detected, and there was no sign of livestock use.

GROUND RECONNAISSANCE RESULTS

Pahranagat South

The majority of this site was affected by a fire prior to the start of the 2010 survey season. The fire removed all understory vegetation and charred the trunks and lower branches of the overstory trees. The site now consists of a stringer of cottonwood, 20 m tall, along a human-made channel that carries the outflow from Upper Pahranagat Lake. The understory contains Indian hemp (*Apocynum cannabinum*) and some small patches of coyote willow (*Salix exigua*) 3 m in height. Canopy closure within the cottonwood stringer is approximately 50%. The channel held water during the site visit in May; surrounding soils were dry. While suitable understory components are now present, they are not currently of sufficient size

to resemble typical occupied willow flycatcher habitat. We recommend reassessing this site in future years. We surveyed the site once, totaling 0.25 observer-hours. No willow flycatchers were detected.

Littlefield, Arizona

In recent years, our survey and monitoring activities focused on Beaver Dam Wash near the Highway 91 Bridge. In December 2010, a flood scoured much of the area, and we evaluated the site (Littlefield Poles) at the beginning of the season for suitability.

GROUND RECONNAISSANCE RESULTS

Littlefield Poles

The site consists of primarily native vegetation and is located on Beaver Dam Wash, immediately upstream of the Highway 91 Bridge. Overall changes to the site as a result of the flood in December 2010 include a reduction in vegetation density and height and a significant change in hydrology. Vegetation along the northern edge of the site consists of a scattered overstory of cottonwood averaging 25 m in height. The previously documented lower strata vegetation of tamarisk and Russian olive (*Elaeagnus angustifolia*) in the cottonwood area are significantly reduced or absent. The southern portion of the site consists of stands of coyote willow and young Goodding willow and cottonwood approximately 5 m in height. These stands have thinned significantly, and canopy closure is now 30 to 50% overall. Extensive sedimentation of the site has also reduced canopy height. No surface water was present in May or June, and the nearest water was Beaver Dam Wash, which was restricted to a channel roughly 80 m from the site. We surveyed the site twice, totaling 1.0 observer-hours. No willow flycatchers were detected. Because of the lack of surface water within the site and the reduction in vegetation density, this site does not currently resemble typical occupied flycatcher breeding habitat. We recommend reassessing the site at the beginning of future breeding seasons.

Mesquite, Nevada

The Mesquite study area is in the floodplain of the Virgin River near Mesquite and Bunkerville, Nevada.

HAFEN LANE

Area: 6.1 ha Elevation: 475 m

This mixed-exotic site lies within the floodplain of the Virgin River in Mesquite, Nevada, between Hafen Lane and the active river channel. Two drainage ditches that pass underneath Hafen Lane flow into the site; the eastern inflow supports a dense stand of cottonwood and Goodding willow, 10 m in height, with some coyote willow 5 m in height in the understory. The western inflow supports a stringer of coyote willow 4–6 m in height and scattered Goodding willow 15–18 m in height, with 70% canopy closure. The coyote willow in the western stringer is of varying health and density. Between the stringers, the site is vegetated by 6-m-tall tamarisk with 90% canopy closure. No water was documented within the site, but damp soils were noted on all visits within the drainage ditches. Tamarisk beetles and heavily defoliated tamarisk were noted at the site in mid-June.

We detected three breeding flycatchers, one of which was a male from Muddy River that displaced the resident male. Portions of the site not known to be occupied were surveyed five times for a total of 16.2 observer-hours. Cowbirds were detected on all surveys, and no sign of livestock use was observed.

MESQUITE WEST

Area: 10.4 ha Elevation: 470 m

This mixed-native site lies within the floodplain of the Virgin River in Mesquite, Nevada. Golf courses and housing developments border the site to the north, and the Virgin River borders the site to the south. This large site is primarily a mosaic of cattail (*Typha* spp.) and bulrush (*Schoenoplectus californicus*) marshes separated by narrow (40–50 m) strips of dense coyote willow with interspersed tamarisk. The coyote willows are generally 5–6 m in height, and canopy closure varies from 50 to >90%. The eastern portion of the site is primarily coyote willow, while the western portion contains a mix of willow and tamarisk. Hydrology at the site is influenced by irrigation runoff from adjacent golf courses and agriculture. The site was regularly inundated through early June. Thereafter, a change in the access point of water into the site diverted all water straight into the Virgin River, bypassing the site altogether. Tamarisk beetles and defoliated tamarisk were noted within the site in mid- to late June.

We detected 10 breeding willow flycatchers and 1 resident, unpaired male. Areas of Mesquite West not known to be occupied by flycatchers were surveyed five times, totaling 7.4 observer-hours. Cowbirds were detected on all surveys. Some signs of cattle were observed early in the season in the eastern portion of the site near the river.

BUNKER MARSH NORTH

Area: 7.1 ha Elevation: 456 m

This mixed-exotic site lies within the floodplain of the Virgin River near Bunkerville, Nevada, approximately 4 km downstream of Mesquite West. The site is between agricultural fields to the southeast and the Virgin River to the northwest. The site is primarily 5–7-m-tall tamarisk, with scattered Goodding willow primarily in the southern portion of the site. Some Goodding willows are also present along the western and northern ends of the site. Canopy closure ranges from 25 to 80%. Surface water was noted within the site in May in a small stream in the northern portion of the site and a small puddle in the center of the site, but no water was noted in mid-June. Dry marshes were present adjacent to the site. Tamarisk beetle larvae but no defoliation were observed in mid-May, and extensive defoliation was observed by mid-June. Surveys at this site were discontinued in mid-June because of the lack of surface water within the vegetation and extensive defoliation. We recommend reassessing the site at the beginning of the next breeding season and discontinuing surveys if the site is dry.

We detected no willow flycatchers. The site was visited twice, for a total of 3.7 observer-hours. Cowbirds were detected on both surveys, and signs of cattle were observed within the site.

Mormon Mesa, Nevada

For approximately 15 km upstream of its confluence with the Muddy River, the Virgin River flows through a 1-km-wide floodplain with a mosaic of habitats, including cattail marshes and tamarisk and willow forest. Much of the area is typically seasonally inundated from snowmelt in the spring and monsoon rains in mid and late summer, and the entire study area experienced severe flooding over the 2004–2005 winter. All the areas surveyed at Mormon Mesa are at least 10 km upstream of the Muddy River confluence. In December 2010, the study area experienced another severe flood. Part of the river shifted its course, and river levels remained elevated (in the 75th percentile) throughout the breeding season, limiting access to portions of the study area during May and early June. Tamarisk beetles and heavy defoliation were noted throughout the study area by mid-July.

MORMON MESA SOUTH

North half: Area: 8.4 ha Elevation: 385 m

South half: Area: 3.4 ha Elevation: 385 m

This mixed-exotic site was split into two contiguous areas to facilitate tracking of survey activity. The site has scattered Goodding willow up to 20 m, but more typically 12–15 m, in height and a patchy understory of tamarisk 3–6 m in height. Dead cattail and arrowweed (*Pluchea sericea*) are present in the understory in this area. Canopy closure is widely variable, ranging from >80% in tamarisk thickets to <50% in openings. There was no surface water within the site, but damp soils were noted in the center of the northern half of the site in May and June. The presence of dead cattails and deadfall suggests that this site was formerly considerably wetter, and portions of the site still have the structure to provide potential flycatcher habitat with wetter soil conditions.

No willow flycatchers were detected. Due to elevated river levels, we surveyed the northern half four times and the southern half three times, totaling 9.3 and 4.8 observer-hours, respectively. Cowbirds were detected on all surveys in the northern half and none of the surveys in the southern half. Signs of cattle were noted within the site on all occasions.

VIRGIN RIVER #1

North half: Area: 11.4 ha Elevation: 380 m

South half: Area: 11.1 ha Elevation: 380 m

Virgin River #1 was also divided into two areas, Virgin River #1 North and Virgin River #1 South, to facilitate streamlining of field logistics. Virgin River #1 North is primarily tamarisk 4–6 m in height, with areas of emergent Goodding willow in the central and southwestern portions of the site. Canopy closure throughout the site is 70–90%. Some surface water was present in June in channels running north to south through the center of the site and in the southwestern corner of the site. By July only a few spots of saturated soil remained in these areas.

We detected four breeding willow flycatchers in the southwestern corner of Virgin River #1 North. We also detected one additional flycatcher for which residency and breeding status could not be determined. Areas of this site not known to be occupied by flycatchers were surveyed four times, totaling 12.9 observer-hours. Cowbirds were detected on all surveys and cattle were observed in the site on multiple occasions.

Virgin River #1 South consists of two disjunct sections; the northern section is immediately south of Virgin River #1 North, while the southern portion is approximately 700 m SSE of Virgin River #1 North. The northern section is primarily tamarisk 4–6 m in height with patches of coyote willow 6 m in height and scattered Goodding willow 8–12 m in height. Canopy closure varies from >90% in areas of dense willow and tamarisk to 25% in marshy openings. The northern section contained standing water throughout the survey season. The southern section consists of tamarisk 6–7 m in height, with a cluster of emergent Goodding willow and dead coyote willow. Canopy closure is 70–90%. Soils in the southern section were dry throughout the survey season. We recommend visiting the southern section at the beginning of the next breeding season and discontinuing surveys in this portion if soils are dry.

We detected 18 breeding willow flycatchers and one unpaired, resident male in the northern section of Virgin River #1 South. We detected two additional willow flycatchers for which residency and breeding status could not be confirmed. Areas of the site not known to be occupied by willow flycatchers were surveyed three times, totaling 5.5 observer-hours. Cowbirds were observed on two surveys, and signs of cattle were observed.

VIRGIN RIVER #2

Area: 11.2 ha Elevation: 380 m

This site received extensive sedimentation from the flood in December 2010. The depth of new sediment ranged from 15 to 60 cm and was most extensive in the southern portion of the site. The site consists of mixed-exotic vegetation with tamarisk 4–6 m in height with a cluster of emergent Goodding willow at the northern end of the site and scattered, emergent Goodding willow at the southern end of the site. Many of the Goodding willow, particularly in the southern third of the site, are dead or dying, and we recommend discontinuing surveys in this portion of the site. Overall canopy closure is 70–90%. The site contained no surface water during the breeding season, though a small area at the very northern end of the site contained damp soil in May and June. The Virgin River, on the eastern edge of the site, had surface water throughout the season.

No willow flycatchers were detected. We surveyed the site five times, totaling 16.8 observer-hours. Cowbirds were observed on all surveys, and cattle sign were observed at the site.

GROUND RECONNAISSANCE RESULTS

Mormon Mesa North

We discontinued surveys after the initial visit at this site in 2010 due to dry conditions and a lack of flycatcher detections since 2005. In December 2010, the study area experienced significant flooding, with the potential to alter the hydrology within the site. We reassessed the site at the beginning of 2011. This site consists of mixed-exotic vegetation, primarily tamarisk 3–5 m in height with areas of emergent Goodding willow up to 12 m in height and patches of coyote willow. Canopy closure varies from 70% in the taller tamarisk to around 50% in the shorter tamarisk. The western edge of the site has a 100 x 50-m patch of Goodding willow, 8 m in height, with up to 75% canopy closure and dead cattails in the understory. Soils were completely dry within the site during a visit in early June, and the nearest water was in the river channel approximately 40 m away. We did not formally survey the site in 2011, though no flycatchers were detected during the site visit. We recommend discontinuing surveys at this site until another flood event occurs that has the potential to alter the hydrology within the site.

Hedgerow

We discontinued surveys after the initial visit at this site in 2010 because of completely dry conditions and a lack of flycatcher detections since surveys began in 2005. In December 2010, the entire study area experienced a significant flood that had the potential to change the hydrology within the site. We reassessed the site at the beginning of 2011. The site is east of Mormon Mesa North, on the eastern side of the Virgin River. It consists of mixed-exotic vegetation with a continuous understory of tamarisk 4–5 m in height and scattered emergent Goodding willow up to 12 m in height. Many of the willows have dead branches. The site is surrounded by tamarisk and arrowweed 2–3 m in height. Canopy closure in the tamarisk varies from about 50% on the edges of the site up to 80% in the denser areas. Soils within the site were completely dry during a visit in May. We did not formally survey the site in 2011, but no flycatchers were detected during the May site visit. We recommend discontinuing surveys at this site until another flood event occurs that has the potential to alter hydrologic conditions.

Muddy River, Nevada

The Muddy River study area is along the Muddy River in the Overton Wildlife Management Area (WMA) near Overton, Nevada.

OVERTON WMA POND

Area: 0.7 ha Elevation: 378 m

This site consists of a patch of mixed-native vegetation approximately 150 m long and 75 m wide at the north end of Overton WMA just south of Honeybee Reservoir. The dominant vegetation consists of 12-m-tall Goodding willow with a sparse 5-m-tall tamarisk understory. Cattail and sedges (*Carex* sp.) are also present on the edges of the site. Arrowweed is present in scattered, dense patches within and along the edges of the site. Canopy closure is variable, ranging up to 90%. A small stream channel runs through the site, and it held surface water throughout the season.

We detected one willow flycatcher for which residency could not be determined. We surveyed the site five times for a total of 2.5 observer-hours. Cowbirds were detected on two visits, and no sign of livestock use was observed.

OVERTON WMA

Area: 14.9 ha Elevation: 378 m

This site consists of a 150-m-wide strip of riparian vegetation spanning both sides of the Muddy River. The site is bordered to the southwest by open agricultural fields and to the northeast by sparser areas of riparian vegetation. The site flooded heavily during the 2004–2005 winter, but vegetation at the site was relatively unchanged. The northern portion of the site is dominated by very dense tamarisk up to 7 m in height with canopy closure of 70–90%. The southern portion of the site consists primarily of a stand of Goodding willow 10–15 m in height with an understory of tamarisk and cattail. Canopy closure in this area is up to 90%. Flowing water was present in the channels of the Muddy River throughout the survey season. Soils in the northern portion of the site outside of the river channel were dry throughout the season. Soils in the southern portion were saturated early in the season and dry at the end of the season in areas adjacent to the channels. Beavers have felled swaths of Goodding willow in the southern portion of the site, resulting in gaps in the canopy. Approximately 0.3 ha of the southern portion of the site was bulldozed in 2005 as part of Overton WMA efforts to repair flood damage to their water control system. Two stretches of the channel of the Muddy River within the site were dredged with heavy equipment over the 2007–2008 winter, resulting in a cleared swath 10–15 m wide on the western bank of the river.

We located 10 breeding willow flycatchers and three unpaired, resident males. We also detected two flycatchers for which residency could not be confirmed. Portions of the site not known to be occupied by flycatchers were surveyed six times, totaling 18.0 observer-hours. We observed no signs of livestock but detected cowbirds on all surveys.

Topock Marsh, Arizona

Topock Marsh lies within Havasu NWR and encompasses over 3,000 ha of open water, cattail and bulrush marsh, and riparian vegetation. A large expanse (over 2,000 ha) of riparian vegetation occupies the Colorado River floodplain between the Colorado River on the western edge of the floodplain and the open water of Topock Marsh on the eastern edge of the floodplain. The vegetation is primarily monotypic tamarisk with isolated patches of tall Goodding willow. Seasonally wet, low-lying areas are interspersed throughout the riparian area. Water levels within Topock Marsh were unusually low in 2011 because the intake valve at the upstream end of the marsh was closed for construction purposes. Feral pigs are present throughout the Topock study area, and evidence of pigs was observed in most survey sites.

PIPES #1

Area: 5.2 ha Elevation: 140 m

This exotic site is bordered to the east by the refuge road and consists primarily of monotypic tamarisk 6–9 m in height. Arrowweed occurs in dense patches within 50 m of the refuge road. The tamarisk is densest within 100 m of the refuge road and becomes more open toward the western edge of the site. The northern edge of the site has the tallest canopy, and there is relatively little deadfall in this area compared to the rest of the site. The central and southern portions of the site have many dead stems and clusters of fallen trees. Canopy closure is 70–90%. The site contained no standing water during the survey season.

We detected one unpaired, resident willow flycatcher from 23 June to 1 July. We surveyed the site five times, totaling 8.5 observer-hours. Cowbirds were detected on all surveys.

PIPES #3

Area: 5.7 ha Elevation: 140 m

This site is bordered to the east by the refuge road. Arrowweed occurs in dense patches within 50 m of the road. Most of the site is vegetated by tamarisk 5–7 m in height. The southeastern portion of the site has a few emergent Goodding willow up to 15 m in height and open areas with marsh vegetation. Canopy closure generally exceeds 70%. The site contained no standing water during the survey season.

We detected two breeding flycatchers and one individual that moved to Pipes #3 after holding a territory in 800M. Portions of Pipes #3 not known to be occupied by flycatchers were surveyed five times, totaling 4.6 observer-hours. Cowbirds were detected on all surveys.

THE WALLOWS

Area: 0.7 ha Elevation: 140 m

The Wallows is primarily vegetated by tamarisk 5–6 m in height with emergent Goodding willow on the western side of the site. The northwestern edge of the site borders an open cattail marsh. The eastern side is dry and grades from 2-m-tall arrowweed along the refuge road to tamarisk up to 8 m in height in the center of the site. Overall canopy closure ranges from 50% in the marshy area to 90% in the tamarisk. Approximately 1% of the site had saturated soil in mid-May, but the site was entirely dry by mid-June.

We detected one resident, unpaired male that moved to The Wallows from Platform. We also detected two individuals for which residency could not be confirmed. Portions of the site not known to be occupied were surveyed five times, totaling 2.1 hours. Cowbirds were detected on three surveys.

PC6-1

Area: 4.8 ha Elevation: 140 m

PC6-1 is a mixed-exotic site consisting primarily of tamarisk 6–7 m in height, with a few patches of arrowweed and cattails present in the understory. A scattered overstory of Goodding willow approximately 10–15 m in height is present in the southwestern corner of the site. Arrowweed 1–2 m in height is present under the willow. A portion of the site within approximately 50 m of the refuge road contains thick stands of arrowweed. Canopy closure in the interior of the site is approximately 90%, while canopy closure on the periphery of the site near the refuge road is approximately 50%. The site was completely dry throughout the survey season.

We detected one willow flycatcher across the road from PC6-1 on 1 June. The site was surveyed five times, totaling 8.1 observer-hours. Cowbirds were detected on all surveys.

PIG HOLE

Area: 2.4 ha Elevation: 140 m

Pig Hole consists of monotypic tamarisk 6–7 m in height, with canopy closure ranging from 70 to 90%. Tamarisk along the northern edge has many wispy branches and smaller diameter stems than the rest of the site. A few dense patches of arrowweed are present on the eastern edge. No standing water or saturated soil was observed within the site during the survey season.

No willow flycatchers were detected. The site was surveyed five times, totaling 5.1 observer-hours. Cowbirds were detected on all surveys.

IN BETWEEN

Area: 7.7 ha Elevation: 140 m

In Between consists of monotypic tamarisk 6–8 m in height. The lowest 3 m of the stand generally lacks foliage, resulting in a relatively open understory. Canopy closure is 70–90%, and the western edge of the site borders a marsh. In Between was affected by water delivery in 2011 (see Chapter 8) and contained varying amounts of surface water through the middle of July.

We detected one flycatcher for which residency could not be confirmed. We surveyed the site five times, totaling 9.9 observer-hours. Cowbirds were observed on four surveys.

800M

Area: 4.7 ha Elevation: 140 m

800M adjoins the western edge of In Between, and the eastern half of the site consists of a cattail and bulrush marsh with clumps of tamarisk 5–7 m in height and scattered, emergent Goodding willow. The remainder of the site is vegetated by tamarisk 4–7 m in height. Canopy closure in the tamarisk is generally >90%, while canopy closure in the marsh is around 50%. 800M was affected by water delivery in 2011 (see Chapter 8) and contained varying amounts of surface water and saturated soil in the marsh through early July.

We located one resident, unpaired male flycatcher and two additional individuals for which residency could not be confirmed. Portions of the site not known to be occupied were surveyed five times, totaling 4.7 observer-hours. Cowbirds were observed on all surveys.

PIERCED EGG

Area: 6.7 ha Elevation: 140 m

This mixed-exotic site borders the western edge of 800M and consists of dense tamarisk 7 m in height, with a scattered overstory of Goodding willow 15 m in height. Areas with willows tend to have a more open understory and contain patches of cattail and bulrush. Overall canopy closure is approximately 80%. The only water or saturated soil within the site was in deep pig wallows.

We detected four flycatchers for which residency could not be confirmed. We surveyed the site five times for a total of 8.5 observer-hours. Cowbirds were observed on all surveys.

SWINE PARADISE

Area: 0.9 ha Elevation: 140 m

Vegetation at this mixed-exotic site consists of tamarisk 6–8 m in height and scattered, emergent Goodding willow up to 15 m in height, with patches of coyote willow. Overall canopy closure is approximately 80%. The northern tip of the site was bulldozed prior to the survey season for a new water conveyance channel. The site was dry throughout the survey season.

We detected one willow flycatcher for which residency could not be determined. We surveyed the site five times, totaling 4.0 observer-hours. Cowbirds were detected on three visits.

BARBED WIRE

Area: 2.1 ha Elevation: 140 m

One large, emergent Goodding willow occurs at the site; otherwise, the site is vegetated by tamarisk 6–10 m in height and of varying density. The northeastern portion of the site contains taller stems, less dead wood in the understory, and fewer large canopy openings than the southwestern portion of the site. A 40-m-wide strip was bulldozed through the center of the site east to west for a new water conveyance channel prior to the start of the survey season. Canopy closure outside the bulldozed area is approximately 70–90%. The only standing water or saturated soil observed in the site was within the new channel.

No willow flycatchers were detected. We surveyed the site five times, totaling 4.0 observer-hours. Cowbirds were detected on four visits.

PLATFORM

Area: 1.9 ha Elevation: 140 m

This site lies between the main refuge road to the west and open bulrush and cattail marsh to the east. Vegetation at the site consists of tamarisk 8 m in height with a few emergent Goodding willow. A narrow line of 5-m-tall coyote willow approximately 5 m wide runs along the eastern edge of portions of the site. Overall canopy closure is approximately 90%. Soils within the site were very dry throughout the survey season.

We detected one resident, unpaired male willow flycatcher. Portions of the site not known to be occupied were surveyed five times, totaling 4.6 observer-hours. Cowbirds were detected on all visits.

250M

Area: 1.9 ha Elevation: 140 m

This site lies between the main refuge road and the open marsh. Vegetation composition and structure varies with distance from the marsh. Closest to the refuge road the site is dominated by mesquite trees (*Prosopis* sp.) with an understory of arrowweed. The center of the site is dominated by tamarisk approximately 7 m in height. Closest to the marsh, the site contains patches of coyote willow and a few emergent Goodding willows approximately 12 m in height. Canopy closure within the site ranges from 70 to 90%. The site was completely dry throughout the survey season.

No willow flycatchers were detected. The site was surveyed five times, totaling 3.3 observer-hours. Cowbirds were detected on three surveys.

HELL BIRD AND GLORY HOLE

Hell Bird: Area: 6.3 ha Elevation: 140 m
Glory Hole: Area: 5.0 ha Elevation: 140 m

These contiguous mixed-exotic sites are located on an island separated from the main riparian area by a narrow, deep channel. Vegetation composition and structure are highly variable, with the survey areas vegetated primarily by a mosaic of tamarisk 6–8 m in height and Goodding willow 15 m in height. Screwbean mesquite (*Prosopis pubescens*) is also scattered throughout the sites. Canopy closure ranges from 50 to 90%. The survey areas are bordered on the west by a sand dune and on other sides by dense bulrush. Areas vegetated by cattail and bulrush are interspersed throughout the survey sites. Extremely low water levels in Topock Marsh resulted in increased accessibility in 2011, and Hell Bird was expanded approximately 100 m to the northeast to encompass areas of coyote willow. Both sites were completely dry throughout the survey season.

We detected 10 flycatchers in Hell Bird for which residency could not be confirmed. No flycatchers were detected in Glory Hole. Hell Bird and Glory Hole were surveyed five times each, totaling 6.0 and 8.3 observer-hours, respectively. Cowbirds were detected during four surveys in each site.

SPAGHETTI

Area: 5.4 ha Elevation: 140 m

Spaghetti is a long, narrow site, generally no more than 30 m wide, running along the Farm Ditch to the west of Glory Hole. The site is vegetated by patches of dense coyote willow up to 7 m in height, scattered Goodding willow up to 12 m in height, and mesquite approximately 8 m in height, with tamarisk interspersed throughout the site. Canopy closure in the coyote willow patches is approximately 80%. Deep water in the ditch made the site inaccessible on foot throughout the survey season, and hydrologic conditions within the site were not assessed.

We detected two willow flycatchers for which residency could not be confirmed. We surveyed this site five times, totaling 3.4 observer-hours. Cowbirds were detected on two visits.

BEAL LAKE

Area: 18.0 ha Elevation: 140 m

This mixed-native restoration site consists of a mosaic of cottonwood, Goodding willow, coyote willow, mesquite, and arrowweed, with some tamarisk scattered throughout the site. Canopy height is highly variable and averages approximately 3–4 m over most of the site and up to 10 m in the cottonwood stands; canopy closure is sparse and averages 35%, reaching 85% in the cottonwood stands. The amount of standing water and saturated soil is highly variable because the site is flood irrigated. Sandy soil at the site allows the water to drain rapidly after irrigation.

We detected one willow flycatcher for which residency could not be confirmed. We surveyed this site five times, totaling 10.6 observer-hours. Cowbirds were detected on all surveys.

LOST LAKE

Area: 3.3 ha Elevation: 140 m

This site consists of a narrow (<100-m-wide) strip of riparian vegetation separated from the Colorado River to the southwest by a low ridge of barren sand dunes and bordered to the northeast by marshy areas. The northern edge of the site consists of an overstory of planted cottonwoods 10–15 m in height, with an

understory of tamarisk 5 m in height, on the edge of a cattail marsh. South of the cottonwoods, the site is primarily tamarisk, 5–8 m in height, with small openings vegetated by arrowweed. Overall canopy closure is approximately 80%. Surface water or saturated soil was present in the marsh on the northern edge of the site throughout the season, but the interior of the site was dry.

We detected one willow flycatcher for which residency could not be confirmed. We surveyed the site five times, totaling 3.4 observer-hours. Cowbirds were detected on four visits.

GROUND RECONNAISSANCE RESULTS

Tractor

This mixed-native site is approximately 1 km north of the inlet ditch at the northern end of Topock Marsh and consists of a 300-m-long stringer of cottonwood 15 m in height with an understory of *Baccharis* sp., mesquite, and 4-m-tall tamarisk bordering a 15-m-wide cattail marsh. The site is bordered by hayfields to the north and south, a dry concrete channel to the west, and a road and a slough to the east. The site was dry during our visit on 26 May except for one small puddle at the far western end of the site, and surveys were discontinued. We visited the site once, totaling 0.3 observer hours. No willow flycatchers or cowbirds were detected. We do not recommend future visits to this site.

Bill Williams River National Wildlife Refuge, Arizona

The Bill Williams River NWR contains the last expanse of native cottonwood-willow forest in the LCR region. The refuge encompasses over 2,500 ha along the Bill Williams River upstream from its mouth at Lake Havasu and contains a mixture of native forest, stands of monotypic tamarisk, beaver ponds, and cattail marsh. Survey sites within Bill Williams are listed below from west to east, moving progressively farther upstream. We did not observe evidence of livestock use at any of the Bill Williams sites.

BURN EDGE

Area: 4.1 ha Elevation: 140 m

Burn Edge is near the northern edge of the Bill Williams riparian corridor, on the eastern edge of an area that burned in 2006. A cattail marsh with Goodding willow and cottonwood 15 m in height runs east-west through the center of the site. This portion of the site also has clumps of tamarisk up to 6 m in height. Canopy closure in the marshy area varies from around 60% at the eastern end to 25% at the western end. The area on either side of the marsh consists of tamarisk 6 m in height with up to 90% canopy closure. An area of the marsh approximately 100 m long was inundated or saturated in May, but only a small puddle remained at the western end of the marsh in June and July.

On 30 June, we detected one willow flycatcher for which residency could not be confirmed. The site was surveyed five times, totaling 6.3 observer-hours. Cowbirds were detected on four visits.

BILL WILLIAMS SITE #4 AND SITE #3

Site #4: Area: 9.9 ha Elevation: 140 m

Site #3: Area: 13.0 ha Elevation: 140 m

These two sites are contiguous and together are known as Mosquito Flats. Vegetation is mixed-native, with an overstory of Goodding willow 15–20 m in height and patches of monotypic tamarisk up to 8 m in height. Patches of coyote willow are also present. Canopy closure is variable and overall is approximately 50%. Stands of cattails and marshy areas occupy approximately 10% of Site #3.

The understory in some areas is very open, and the ground in these areas is covered with herbaceous vegetation. Many large willows and cottonwoods have fallen over the past several years, leaving large gaps in the canopy and creating patches of thick, dead, fallen woody vegetation. Mosquito Flats had a network of small, flowing streams with some open marshes in May. By mid-June, the streams and marshes were muddy but contained no standing water, and the only surface water remaining was in a deep, backwater channel on the western side of Site #4.

We detected one resident, unpaired flycatcher and two flycatchers for which residency could not be confirmed in Site #4. Two breeding flycatchers and one individual for which residency could not be confirmed were detected in Site #3. Portions of the sites not known to be occupied by flycatchers were visited five times, totaling 16.8 observer-hours at Site #4 and 19.6 observer-hours at Site #3. Cowbirds were detected on all surveys of Mosquito Flats.

LAST GASP

Area: 2.1 ha Elevation: 140 m

Last Gasp is a narrow, mixed-native site along a channel on the northern edge of the Bill Williams riparian area, approximately 250 m east of Burn Edge. Vegetation within the site consists of a broken overstory of cottonwood and Goodding willow 15–20 m in height and a tamarisk understory 5–7 m in height. Canopy closure varies from 50% in the channel to 80–90% in the surrounding tamarisk. Surface water was present in ponds and puddles within the channel in May. One small puddle remained in mid-June, and the site was completely dry in July.

No willow flycatchers were detected at Last Gasp. We surveyed the site five times, totaling 4.6 observer-hours. Cowbirds were detected on all visits.

BILL WILLIAMS SITE #5

Area: 6.8 ha Elevation: 143 m

Site #5 is located on the eastern edge of the Bill Williams River floodplain and is bordered to the northeast by steep cliffs and to the west by a dry river channel. Vegetation in the site is mixed-native, with Goodding willow and cottonwood 15–20 m in height in the overstory. The understory consists of tamarisk 7 m in height as well as some young Goodding willow and cottonwood. Ground cover in portions of the site consists of thick, dead, fallen woody vegetation. Canopy closure in the site is variable, ranging from 25% in open areas to 70–90% in the denser vegetation. Standing water was present throughout the survey season along the northeastern edge of the site in the form of a small stream with deep beaver ponds. Soils in the majority of the site were dry.

We detected one willow flycatcher on 21 May and one individual on 29 May; residency could not be determined for these individuals. We surveyed the site five times, totaling 8.9 observer-hours. Cowbirds were detected on all surveys.

COUGAR POINT

Area: 1.3 ha Elevation: 157 m

This site was visited in early July after personnel from an unrelated field crew reported hearing a willow flycatcher singing. The site consists of dense, young, even-age stands of Goodding willow and cottonwood approximately 6 m in height along a channel of the Bill Williams River. Seep willow (*Baccharis salicifolia*) is present in the understory but appears to be dying back as it becomes shaded by the taller cottonwoods and willows. Cattail marshes are present within and around the site. Canopy

closure within the woody vegetation exceeds 80%. Surface water was present within the marshes and the woody vegetation when the site was visited in July and August.

We detected one nesting female flycatcher, but the male was not detected during nest monitoring visits. No formal surveys were completed.

UPSTREAM FROM SITE #8

Area: 1.5 ha Elevation: 170 m

Vegetation in the majority of the site consists of an overstory of cottonwood and Goodding willow up to 15 m in height and an understory of tamarisk. The western third and southern edge of the site are vegetated by Goodding willow and cottonwood up to 10 m in height. The eastern third is dominated by dry tamarisk 4–6 m in height with scattered, emergent Goodding willow and cottonwoods. The northern edge of the site borders a cattail marsh. Canopy cover is variable and ranges from 50 to 80%. The western portion of the site contained surface water throughout the breeding season.

We detected no willow flycatchers. We surveyed the site five times, totaling 5.1 observer-hours. Cowbirds were detected on two visits.

PLANET RANCH ROAD

Area: 3.3 ha Elevation: 170 m

This mixed-native site follows the Bill Williams River at the southern edge of the riparian area. The vegetation immediately adjacent to the river is dominated by Goodding willow and cottonwood up to 15 m in height. Both riverbanks are steep, and vegetation on top of the banks more than a few meters from the water is dominated by arrowweed and tamarisk 4–5 m in height. Canopy closure within the site is highly variable, ranging from <50% on the dry banks to 90% within dense willow and cottonwood stands. The river had surface water throughout the survey season and was impounded in multiple locations by beaver dams.

We detected three breeding willow flycatchers and two individuals for which residency could not be confirmed. Portions of the site not known to be occupied by flycatchers were surveyed five times, totaling 12.0 observer-hours. We detected cowbirds on four surveys.

NEW RIVER

Area: 0.6 ha Elevation: 180 m

We first visited this site in 2008, at which time the vegetation appeared too young and sparse to support willow flycatchers, and determined that the site should be reevaluated in future years. The site consists of narrow stringers of cottonwood and Goodding willow along both sides of a channel of the Bill Williams River. Some patches of vegetation reach 8 m in height, but average height is approximately 5 m. Vegetation closest to the water is typically 3–4 m in height with 90% canopy closure, while the cottonwoods and willows on the periphery of the site reach 8 m in height but only 25% canopy closure. Soils within and around the site are very sandy. The western portion of the site contained surface water within the river channel throughout the survey season. Vegetation at the site has matured somewhat since the visit in 2008 but still lacks the combination of extent, size, and density typical of occupied flycatcher habitat. The site should be reevaluated in another two or three years.

No willow flycatchers were detected. We surveyed the site five times, totaling 3.9 observer-hours. Cowbirds were detected on one survey.

GROUND RECONNAISSANCE AND OPPORTUNISTIC SURVEY RESULTS

Wispy Willow

This site is approximately 200 m downstream of Site #1 along the north bank of the Bill Williams River. The site consists of a patch of coyote willow approximately 60 x 30 m in size. Canopy height is 4–5 m, and stem diameter is generally ~ 3 cm. Canopy closure is 70–90%. Water from the channel extended under the willows during the site visit in May. The vegetation is not currently of sufficient size to resemble typical occupied willow flycatcher habitat along the LCR, but the site should be evaluated in future years. We surveyed the site three times, totaling 2.8 observer-hours. We detected one flycatcher on 27 May between Wispy Willow and Site #1.

Site #1, Site #2, and Site #11

These sites are scheduled for biennial surveys in 2012. We completed one opportunistic survey on 13 June at each site, as the field schedule allowed. All three sites are at the mouth of the Bill Williams River, along an arm of Lake Havasu that follows the river channel, and are vegetated by Goodding willow and cottonwood up to 20 m in height and an understory of tamarisk. Canopy closure is approximately 70%. No flycatchers were detected, but cowbirds were detected at all three sites. The survey totaled 1.8 observer-hours for the three sites combined.

Mineral Wash and Beaver Pond

These sites are scheduled for biennial surveys in 2012. We completed one opportunistic survey on 12 June at each site, as the field schedule allowed. Mineral Wash and Beaver Pond are adjacent sites, approximately 3 km upstream of Site #5, and follow channels of the Bill Williams River. Both sites contain mixed-native vegetation consisting of an overstory of Goodding willow and cottonwood up to 18 m in height and an understory of tamarisk averaging 5 m in height. Each site contained surface water within at least one river channel at the time of the survey. We detected no willow flycatchers but did detect cowbirds at both sites. The survey of Mineral Wash and Beaver Pond totaled 2.3 and 5.5 observer-hours, respectively.

Palo Verde Ecological Reserve, California

PVER PHASE 2

Area: 21.4 ha Elevation: 85 m

This habitat creation site is vegetated with a mosaic of cottonwood, Goodding willow, and coyote willow, which reach heights of 10, 8, and 5 m, respectively. Height and density of the vegetation varies within and between cells of the site. Canopy closure is highly variable, ranging from <25 to 85%. The entire site has a ground covering of alfalfa (*Medicado sativa*). The site is flood irrigated and contained surface water in a portion of the site during one visit in June.

We detected three willow flycatchers on 16 May, six on 26 May, and two on 9 June. One of the flycatchers detected on 9 June was determined to be color-banded. The combination could not be confirmed with 100% confidence, but it was likely an individual originally banded in southern Nevada. We could not relocate the banded individual on subsequent visits to the site. We surveyed the site six times, totaling 16.5 observer-hours. Large numbers of cowbirds were detected on all visits, and no evidence of livestock use was recorded.

PVER PHASE 3

Area: 21.4 ha Elevation: 85 m

This habitat creation site is vegetated with a mosaic of rectangular cells of cottonwood, Goodding willow, and coyote willow that reach heights of approximately 10, 5, and 4 m, respectively. Height and density of the vegetation varies within and between the cells of the site. Canopy closure is highly variable, ranging from 50 to 80%. The entire site has a ground covering of alfalfa. The site is flood irrigated and contained surface water in approximately one quarter of the site on visits in June and July.

We detected one willow flycatcher on 16 May and three on 26 May. We surveyed the site six times, totaling 14.5 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock was recorded.

Cibola, Arizona and California

CVCA PHASE 1

Area: 26.2 ha Elevation: 73 m

This habitat creation area consists of a mosaic of rectangular cells of cottonwood, Goodding willow, and coyote willow of varying size and density. Each cell generally contains a single species and age class. The tallest cottonwoods and willows are around 12 m in height, and canopy closure in the densest areas is 85–90%. Coyote willow reaches 3–6 m in height. The site is flood irrigated and contained standing water in approximately 20% of the site during visits in May and July. The Colorado River is about 100 m from the northern edge of the site; the southern edge is adjacent to CVCA Phase 2; and the remaining two sides are surrounded by agriculture. The irrigation canal adjacent to the site held surface water throughout the season.

We detected six willow flycatchers on 23 May, three on 31 May, and three on 8 June. The site was surveyed six times, totaling 16.0 observer-hours. Large flocks of cowbirds were detected on all visits, and no evidence of livestock use was observed.

CVCA PHASE 2

Area: 25.5 ha Elevation: 73 m

This habitat creation area consists of a mosaic of rectangular cells of cottonwood, Goodding willow, and coyote willow of varying size and density. The tallest cottonwoods and Goodding willow reach approximately 12 m, and canopy closure reaches 95% in the densest areas. Coyote willow reaches 3–6 m in height. The site is flood irrigated but did not contain standing water during any of our site description visits. The northern edge of the site is adjacent to CVCA Phase 1, and the remaining sides are surrounded by agriculture. The irrigation canal adjacent to the site held surface water throughout the season.

We detected 11 willow flycatchers on 23 May. The site was surveyed six times totaling 16.0 observer-hours. Large flocks of cowbirds were detected on all visits, and no evidence of livestock use was observed.

CVCA PHASE 3

Area: 38.4 ha Elevation: 73 m

This habitat creation area consists of a mosaic of rectangular cells of cottonwood, Goodding willow, and coyote willow of varying size and density. The tallest cottonwoods reach approximately 10 m in height,

Goodding willows reach 7 m, and coyote willows reach 4 m. Canopy closure varies from 20 to 80%. The site is flood irrigated and contained surface water during a visit in June. The irrigation canal adjacent to the site held water during a visit in July. The site is surrounded by agricultural fields.

We detected 16 willow flycatchers on 24 May and 2 on 1 June. The site was surveyed five times, totaling 14.0 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

CIBOLA NATURE TRAIL

Area: 13.7 ha Elevation: 70 m

This habitat creation site consists of a mosaic of cottonwood, Goodding willow, and mesquite. Approximately half the site consists of scattered screwbean and honey mesquite (*Prosopis glandulosa*) up to 5 m in height with a thick understory of Emory baccharis (*Baccharis emoryii*). The northern half of the site contains an extensive stand of Goodding willow 8 m in height. The northern edge of the willow stand has canopy closure <25%, and many of the willow are dead. The southern half of the willow stand has canopy closure around 70%. The southwestern corner of the site has a small stand of cottonwoods, and stringers of cottonwoods up to 18 m in height occur throughout the site. The site is flood irrigated but did not contain surface water during any of our site description visits.

We detected one willow flycatcher on 1 June. The site was surveyed five times, totaling 6.0 observer-hours. Large numbers of cowbirds were detected on all surveys, and no evidence of livestock use was observed.

CIBOLA ISLAND

Area: 4.2 ha Elevation: 70 m

This mixed-native site is approximately 9.5 km southwest of Cibola Nature Trail. Dirt roads border the site to the north, east, and west. Open farm fields lie to the east and west, with irrigation channels alongside the roads. An irrigation canal empties into the northern end of the site, creating an open, marshy area down the center of the site. Between this marshy area and the western road, vegetation consists of an overstory of Goodding willow 10–12 m in height with an understory of tamarisk 5–7 m in height. Canopy closure within the willows is 80%. The eastern edge of the marsh is lined with a narrow strip of tamarisk 5–6 m in height with a few emergent Goodding willows on the marsh edge. Between the tamarisk strip and the eastern road, vegetation consists of honey mesquite and bushy arrowweed. The marsh was dry in mid-June and mid-July but had some surface water in early July. The irrigation canal running along the northern border of the site held water in mid-July. This site burned in a fire that started at the end of August.

No willow flycatchers were detected. The site was surveyed three times, totaling 2.3 observer-hours. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

CIBOLA SITE #2 AND CIBOLA SITE #1

Cibola Site #2: Area: 16.4 ha Elevation: 65 m

Cibola Site #1: Area: 7.7 ha Elevation: 65 m

These adjacent, mixed-exotic sites consist of a 200-m-wide strip of riparian vegetation between the channelized Colorado River to the west and a levee road to the east. Woody vegetation consists of a mix of tamarisk and arrowweed, 3–4 m in height, which is dry and scrubby on the eastern edge of the sites and becomes denser toward cattail marshes on the western edge of the sites. Emergent Goodding willow and

cottonwood are scattered along the eastern edge of the marshes. Overall canopy closure is less than 50%. The marshes contained surface water throughout the survey season.

We detected three willow flycatchers at Cibola Site #2 on 25 May and two on 14 June. No willow flycatchers were detected at Cibola Site #1. We surveyed each site five times, totaling 6.2 and 4.1 observer-hours for Cibola Site #2 and Cibola Site #1, respectively. Cowbirds were detected on all surveys, and no evidence of livestock use was observed.

CIBOLA LAKE EAST

Area: 4.5 ha Elevation: 64 m

This site borders the marsh on the eastern edge of Cibola Lake. Vegetation within the site consists primarily of tamarisk. Within 30 m of the marsh edge, tamarisk reaches 6–7 m in height and 90% canopy closure. As distance from the marsh increases, the height and density of the tamarisk decreases, and the tamarisk becomes mixed with arrowweed. Soil within the site was dry throughout the survey season.

We detected one willow flycatcher on 25 May and one on 20 June. The site was surveyed five times, totaling 5.0 observer-hours. Cowbirds were detected on four visits, and burros were heard on the periphery of the site.

WALKER LAKE

Area: 11.4 ha Elevation: 64 m

This mixed-exotic site is located along the northeastern edge of Walker Lake. The majority of the site consists of very dense tamarisk approximately 5 m in height with 90% canopy closure. The southeastern end of the site contains scattered emergent Goodding willow up to 20 m in height, as well as a couple of emergent cottonwoods. This portion of the site also contains a small opening with dead cattails and a small patch of half-dead coyote willow. Walker Lake contained standing water and saturated soil throughout the survey season, and the interior of the southern end of the site also contained surface water in both June and July.

We detected one willow flycatcher on 15 June. The site was visited three times, totaling 4.9 observer-hours. Cowbirds were detected on two surveys, and no evidence of livestock use was observed.

Imperial, Arizona and California

PARADISE

Area: 7.8 ha Elevation: 62 m

The center of this mixed-native site consists of stringers of cottonwood and Goodding willow 15–20 m in height. Tamarisk (5 m in height) and arrowweed (3 m in height) make up the understory. The cottonwoods and willows are separated from the Colorado River by a 50-m-wide strip of dense tamarisk. A marsh borders the western side of the southern third of the site. This marsh had been vegetated by cattails in previous years but now consists primarily of common reed (*Phragmites australis*). Canopy closure within the site is variable. Standing water was present within the marsh in May.

We detected three willow flycatchers on 18 May. The site was surveyed three times, totaling 3.3 observer-hours. Cowbirds were detected on every visit, and no evidence of livestock was noted.

HOGE RANCH

Area: 20.7 ha Elevation: 61 m

This mixed-exotic site borders the Colorado River and is dominated by tamarisk 4–6 m in height, with a few emergent cottonwood and Goodding willow (15 to 18 m in height) at the southern end of the site near the old ranch. Linear marshes with cattail, bulrush, and common reed occupy less than 20% of the interior of the site, and there are a few patches of coyote willow. Canopy closure is variable and reaches 70–90% in areas of dense, woody vegetation. The marshes in the interior of the site were inundated in June and July.

We detected eight willow flycatchers on 21 May and six on 2 June. The site was surveyed five times, totaling 5.9 observer-hours. Cowbirds were detected on every visit, and burros were heard near the site.

RATTLESNAKE

Area: 7.6 ha Elevation: 60 m

This mixed-exotic site is a patchwork of tamarisk 7 m in height with emergent Goodding willow up to 15 m in height and strips of dense coyote willow 6–8 m in height. Dense deadfall and debris within the coyote willows reduce the suitability of the area for willow flycatchers. Canopy closure is 70–90%. Extensive cattail marshes separate this site from the Colorado River. Standing water was present in the interior of the site in June.

We detected three willow flycatchers on 21 May and two on 2 June. The site was surveyed five times, totaling 6.4 observer-hours. Cowbirds were detected on all surveys, and burros were heard at the site.

MILEMARKER 65

Area: 10.0 ha Elevation: 58 m

The site is a narrow strip of mixed-exotic vegetation between the Colorado River and a backwater marsh. Vegetation at the site consists primarily of dense tamarisk 6 m in height. Dense common reed, approximately 3 m in height, also occurs throughout the site and together with the tamarisk creates almost complete canopy closure. Because of the impenetrable vegetation at the site, we surveyed it from the river, and hydrologic conditions in the interior of the site during the surveys are unknown.

We detected one willow flycatcher on 18 May. We surveyed the site twice for a total of 0.9 observer-hours. Cowbirds were detected on both visits, and no evidence of livestock use was observed.

NURSERY NW

Area: 7.0 ha Elevation: 58 m

This mixed-exotic site lies between the Colorado River and a cattail marsh. The dominant vegetation is tamarisk approximately 5 m in height with an understory of common reed. Mesquite trees are scattered along the western edge of the site. The eastern edge of the site, adjacent to the cattail marsh, has a stand of Goodding willow 9 m in height. Overall canopy closure is around 70%, and the densest portions of the site have canopy closure >90%. Surface water was present in marsh and the eastern edge of the site throughout the survey season.

We detected four willow flycatchers on 22 May and two on 5 June. The site was surveyed five times, totaling 6.9 observer-hours. Cowbirds were detected on four visits, and there was no evidence of livestock use.

FERGUSON LAKE

Area: 21.1 ha Elevation: 57 m

The Ferguson Lake site is on a strip of land between Ferguson Lake and the Colorado River. Vegetation is mixed-native, with scattered, emergent Goodding willow 10 m in height along the western edge of the site bordering Ferguson Lake. Tamarisk 5–6 m in height is the dominant understory species, and it forms a continuous canopy in portions of the site. The site also contains patches of arrowweed with scattered screwbean mesquite and little canopy cover. The western edge of the site up to 50 m from the lakeshore had standing water in June and July.

We detected two willow flycatchers on 19 May. The site was surveyed three times, totaling 7.4 observer-hours. Cowbirds were detected on all visits, and no signs of livestock use were observed.

GREAT BLUE HERON

Area: 7.1 ha Elevation: 58 m

This site, on the eastern shore of Martinez Lake, consists of mixed-exotic vegetation. Near the shore of Martinez Lake, Goodding willow forms an overstory 15 m in height, with an understory of tamarisk, common reed, and giant reed (*Arundo* sp.). Canopy closure in this area is 80%. Portions of the site contain thickets of willow deadfall. Farther from the lake, the site is vegetated by scattered arrowweed and tamarisk 6 m in height, with canopy closure <50%. Soils within the site were dry throughout the survey season.

We detected three willow flycatchers on 17 May, nine on 20 May, four on 3 June, and five on 5 June. The site was surveyed five times, totaling 15.9 observer-hours. Cowbirds were detected on all visits, and burros were detected on the periphery of the site.

POWERLINE

Area: 1.0 ha Elevation: 58 m

This mixed-native site consists of a strip of Goodding willow and cottonwood along the border of a cattail marsh. Overstory height is approximately 12 m and canopy closure is approximately 50%. Tamarisk and arrowweed are present in the understory, and honey mesquite is mixed with the tamarisk on the upland edge of the site. Surface water was present in the marsh and in the southern portion of the site in May and June.

We detected two willow flycatchers on 17 May and one on 3 June. We surveyed the site five times, totaling 4.2 observer-hours. Cowbirds were detected on all visits, and burro tracks and scat were noted within the site.

MARTINEZ LAKE

Area: 4.6 ha Elevation: 58 m

This mixed-native site borders the eastern shore of Martinez Lake. The eastern edge of the site, adjacent to the upland, is dominated by arrowweed with scattered Goodding willow, cottonwood, and tamarisk. Goodding willow <10 m in height and cottonwood up to 15 m in height are more prevalent on the western edge of the site, adjacent to cattails and common reed along the lakeshore. Canopy closure is highly variable. The western edge of the site contained saturated soil in May and surface water in June.

We detected two willow flycatchers on 3 June. We surveyed the site five times, totaling 8.8 observer-hours. Cowbirds were detected on all visits, and burros were heard on the periphery of the site.

Mittry Lake, California

MITTRY WEST

Area: 4.4 ha Elevation: 48 m

The center of this mixed-native site is dominated by Goodding willow 12 m in height with a dense understory of arrowweed and tamarisk. Deadfall is common throughout the site, and canopy closure varies from 30 to 70%. Honey and screwbean mesquite are scattered throughout the site but are more common near the periphery. A clump of coyote willow 6 m in height and 50 m in diameter is present in the northeastern corner of the site. Surface water was extensive in the site in May with a few puddles remaining in June.

We detected three willow flycatchers on 17 May. The site was visited three times, totaling 4.3 observer-hours. Cowbirds were detected during all surveys, and no evidence of livestock use was observed.

GROUND RECONNAISSANCE RESULTS

Laguna

Laguna encompasses 449 ha between Imperial and Laguna Dams, on the east side of the Laguna dredge discharge area. This area will be included in future riparian restoration efforts, and we evaluated the existing habitat to determine whether it is suitable for willow flycatchers. Vegetation at the site consists primarily of tamarisk < 4 m in height, arrowweed, and quail bush (*Atriplex lentiformis*). A small cattail marsh is present on the eastern edge of the site; surrounding vegetation consists of tamarisk, arrowweed, and a few 5-m-tall Goodding willow. A patch of Goodding willow 7 m in height with an understory of common reed and tamarisk is present along an old backwater channel in the north-central part of the site, but soils in this area were completely dry during the site visit on 6 June. Overall, the site is lacking in vegetation of sufficient height and density to resemble suitable flycatcher habitat, and surface water was present only in one small area. Soils in most of the site were complete dry. We visited the site once, for a total of 8.0 observer-hours. No willow flycatchers were detected. We discontinued surveys after the initial visit because of the complete lack of potential flycatcher habitat.

Yuma, Arizona

GILA RIVER SITE #2

Area: 2.9 ha Elevation: 45 m

The center of this mixed-native site consists of an overstory of cottonwood up to 15 m in height and Goodding willow approximately 8 m in height, with an understory of arrowweed. Canopy closure in the center of the site is approximately 50%, and there is deadfall in the understory. The remainder of the site is vegetated by tamarisk 4 m in height and arrowweed, with canopy closure <50%. The site is bordered to the north by agricultural fields and to the south by an open, sandy area vegetated by arrowweed. There was no standing water within the vegetation during the survey season, but the northwestern edge of the site borders a marsh, which held water throughout the season.

We detected seven willow flycatchers on 4 June. The site was surveyed four times, totaling 5.3 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

FORTUNA SITE #1

Area: 3.2 ha Elevation: 45 m

This mixed-native site consists of a narrow strip of cottonwood and Goodding willow up to 15 m in height with 50–70% canopy closure. Tamarisk and arrowweed form a patchy understory on the periphery of the site. Within the densest cottonwood/willow areas, there is little understory but many downed branches. The site is bordered to the north by agricultural fields and to the south by a cattail marsh and the Gila River. The interior of the site was dry in June and July, but the adjoining marsh contained surface water.

We detected 15 willow flycatchers on 4 June. We surveyed the site four times, totaling 6.1 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

FORTUNA NORTH

Area: 3.8 ha Elevation: 46 m

This site is vegetated primarily by mature tamarisk approximately 7 m in height. Goodding willow and mesquite, also 7 m in height, are scattered throughout the site but make up less than 10% of the vegetation. Canopy closure is approximately 80% in the densest areas. The Gila River runs along the western edge and through the northwestern corner of the site. No surface water was noted within the woody vegetation during the survey season, but the river contained water.

We detected six willow flycatchers on 4 June and one on 5 June. We surveyed the site four times, totaling 9.5 observer-hours. Cowbirds were detected on all visits, and no evidence of livestock use was observed.

NDOW Study Areas

Field personnel spent 1.0 observer-hour completing broadcast surveys for willow flycatchers at 3 of 19 sites at Key Pittman WMA, River Ranch, and Warm Springs Natural Area. The remaining 17 sites were occupied by resident flycatchers from the beginning of the season and were monitored but not surveyed. Willow flycatcher survey and monitoring results are summarized in Table 2.7 and are presented below along with site descriptions. Details of occupancy, pairing, color-banding, and breeding are presented in Chapters 3 and 4. The boundaries of survey sites and occupancy in 2011 are shown on orthophotos in Appendix B.

In addition to willow flycatcher surveys, field personnel spent 9.0 observer-hours completing broadcast surveys for Yellow-billed Cuckoo at both Key Pittman and River Ranch. The results of cuckoo surveys are summarized below.

Table 2.7. Willow Flycatcher Detections at NDOW Study Areas, 2011

Study Area[1]	Survey Site	Area (ha)	Number Detected (Date(s) of Detection)[2,3,4,5]
KEPI	Patch 0	0.04	2 (6 Jun–8 Aug)
	Patch 1	0.1	2 (29 May–4 Aug)
	Patch 2	0.1	2 (18 May–8 Aug)
	Patch 3	0.1	1 (16 May–27 Jul)[6], 1 (31 Jul)
	Patch 4	0.1	2 (25 May–31 Jul), 3 (27 Jul)[6,7]
	Patch 4.5	0.02	ND

Table 2.7. Willow Flycatcher Detections at NDOW Study Areas, 2011 (Continued)

Study Area[1]	Survey Site	Area (ha)	Number Detected (Date(s) of Detection)[2,3,4,5]
KEPI	Patch 5	0.1	2 (21 May–11 Aug)
	Patch 6	0.2	2 (16 May–6 Jul), 3 (18 Jun–31 Jul), 1 (12 Jul)[8]
	Patch 7	0.1	2 (16 May–11 Aug)
	Patch 8	0.1	2 (1 Jun–4 Aug)

	East Side	0.4	2 (15 Jun–27 Jul)
	Smalls	0.5	1 (15 Jun–16 Jul), 1 (27–29 Jun)
WMSP	Muddy Mac	0.7	2 (15 May–28 Jul), 3 (26 May)

[1] KEPI = Key Pittman WMA, RIRA = River Ranch, WMSP = Warm Springs Natural Area.

[2] ND = No willow flycatchers were detected.

[3] See Chapter 3 for details on territories, residency, pairing, and color-banding; see Chapter 4 for details on nesting activity.

[4] Flycatchers in territories that were occupied throughout the breeding season are shown as being present throughout the season. Flycatchers detected on a single occasion or for a short period of time are listed separately.

[5] We detected several within-season movements between study areas in 2011. See Table 3.9 for details.

[6] One individual detected 16 May–27 Jul in Patch 3 and recaptured 27 Jul in Patch 4.

[7] One individual detected 26 Jun in Patch 10.5 and recaptured 27 Jul in Patch 4

[8] This individual detected 30 Jun in Patch 11 and12 Jul in Patch 6.

[9] One individual recaptured 26 Jun in Patch 10.5 and 27 Jul in Patch 12.

[10] Not an official survey site. Incidental detections recorded.

Key Pittman Wildlife Management Area, Nevada

PATCHES 0–12

Area: 1.4 ha Elevation: 1,169 m

This study area is divided into 15 small stands of coyote willow. These stands form a strip of habitat between bulrush marsh on the edge of Nesbitt Lake to the east and dry upland scrub dominated by saltbush and grasses to the west. Most of the stands are independent of each other, but four stands (Patches 6–9) have grown together, forming a larger contiguous stand. Each stand is characterized by very dense, large-diameter stems of coyote willow. Some areas have fallen or leaning stems with wispy growth in the lower 2 m, making traversing those areas difficult. Canopy height ranges from 4 to 8 m with the taller stems occurring in the center of each site, giving each stand a rounded look. Canopy closure is 70–90%. Surface water was present along the eastern edge in May and June, though no more than 10% of the area within the sites was inundated, with an additional 5% saturated. Soils were damp in July with no saturated soil or standing water.

We located 33 breeding willow flycatchers across 13 of the 15 sites. We detected one resident, unpaired male and an additional seven individuals for which we could not determine residency. An additional individual of undetermined residency was detected on a fence adjacent to the sites. Only the unoccupied site, Patch 4.5, was surveyed, totaling 0.3 observer-hours. Cowbirds were detected during one survey but were noted throughout the season during nest monitoring activities. Signs of cattle were present in the dry upland scrub, but the sites have been fenced off to prevent damage. Deer were present within the sites, but do not appear to heavily impact the vegetation structure.

YELLOW-BILLED CUCKOO SURVEYS

We completed four surveys for Yellow-billed Cuckoo at Key Pittman, totaling 6.5 observer-hours. The first survey included Patches 0–4.5 as well as the cottonwood stand at the southern end of Nesbitt Lake. The final three surveys covered the cottonwood stand and Patches 0–12. No Yellow-billed Cuckoos were detected.

River Ranch

River Ranch is in the Pahranagat Valley, approximately 12 km south of Key Pittman, and consists of several isolated patches of vegetation. Each patch is surrounded on all sides by grazed, irrigated cattle pasture, and the perimeter of each site has a distinct browse line at 1.5 m in height.

WEST SIDE

Area: 0.3 ha Elevation: 1,100 m

This site is composed primarily of dense, large-diameter coyote willow 7 m in height. Shorter coyote willow approximately 4 m in height is present around the perimeter, giving the site a rounded look. A gap 3 to 5 m wide runs diagonally through the site from the northwestern to the southeastern corner. Some Russian olive is scattered along the perimeter of this gap. There is little to no understory, except where willows are regenerating and in the gap, where grasses and other herbaceous plants dominate. Canopy closure is 90% throughout most of the site, except in the gap where it varies from 0 to 30%. Areas of deadfall up to 1 m deep are scattered throughout the site, making travel difficult in places. Water levels fluctuated throughout the season depending on irrigation activity. Maximum water extent included flowing, 10-cm-deep water covering approximately 50% of the site, saturated soils covering an additional 30%, and 20% with damp soils. Minimum water extent included damp soils throughout the site. Water tended to pool in a ditch approximately 1 m wide and 0.2 m deep surrounding the site.

We detected two breeding flycatchers and one male for which breeding status could not be confirmed. We also detected an additional two individuals for which residency could not be determined. Due to flycatcher occupancy, this site was surveyed only once, totaling 0.4 observer-hours. No cowbirds were detected during the survey, but they were noted intermittently throughout the breeding season in low numbers. Signs of cattle were present in and surrounding the site, but the cattle do not appear to use the interior of the site extensively.

EAST SIDE

Area: 0.4 ha Elevation: 1,100 m

This site is composed primarily of dense, large-diameter coyote willow 6 to 7 m in height. Tree height is shorter at the perimeter, giving the site a rounded appearance. Russian olive and velvet ash (*Fraxinus velutina*) occur in low numbers. There are numerous piles of deadfall scattered throughout the site. Little to no understory is present, except where the willow is able to regenerate and also in some small clearings

where herbaceous vegetation dominates. Canopy closure is primarily 70–80%, except in a few scattered clearings where it ranges from 0 to 25%. Water levels fluctuated throughout the season depending on irrigation activity. Maximum water extent included damp to almost saturated soils throughout and a ditch of water 1 m wide and 0.2 m deep surrounding the site. Minimum water extent included dry soils throughout the site.

We detected two breeding flycatchers. Due to flycatcher occupancy, no formal surveys were conducted. Brown-headed cowbirds were noted intermittently throughout the breeding season in low numbers. Signs of cattle were present throughout and surrounding the site, with cattle trails throughout the interior of the site.

SMALLS

Area: 0.5 ha Elevation: 1,100 m

This site is composed primarily of coyote willow 5 m tall. There is little understory except sparse, regenerating willow in the densely vegetated areas. A large gap in the vegetation, totaling approximately 25% of the site, dominates the northern half of the site. This gap is ringed by a stand of shorter coyote willow approximately 4 m in height and 4 m wide on the western, northern, and eastern sides. Canopy closure averages 80-85% in the vegetated areas. Deadfall is scattered throughout the site but typically does not occur in piles as it does in West Side and East Side. Water levels were variable throughout the season depending on irrigation activity. Maximum water extent included a pool of water at the northern end of the site and saturated soils throughout the remainder of the site. Minimum water extent included completely dry soils throughout the site.

We detected one male for which breeding status could not be confirmed and an additional individual for which we could not determine residency. Due to flycatcher occupancy, this site was surveyed only once, totaling 0.4 observer-hours. No cowbirds were detected during the survey, though they were noted at other times during the breeding season. Signs of heavy cattle use were present throughout the site.

YELLOW-BILLED CUCKOO SURVEYS

We completed three surveys for Yellow-billed Cuckoo at River Ranch, totaling 2.5 observer-hours. All suitable habitat was covered in each survey. No Yellow-billed Cuckoos were detected.

Warm Springs Natural Area

On 1 July 2010, a wildfire burned at least part of all the survey sites at Warm Springs. At the beginning of the breeding season of 2011, ground reconnaissance was conducted at all sites to assess the extent of the damage and suitability of habitat for flycatchers. The degree of damage varied from site to site and ranged from almost complete consumption of all vegetation to consumption of the understory with overstory structure intact but the canopy reduced by 80–90%. Regeneration of woody vegetation was noted at all sites, but vegetation was generally sparse and less than 2 m in height. One site was partially damaged in the fire with the remainder largely undamaged. Due to the degree of fire damage, surveys were discontinued at all sites except for the one partially damaged site.

MUDDY MAC

Area: 0.7 ha Elevation: 548 m

This native site is near the head of Apcar Stream. The northern portion of the site was heavily damaged in the 2010 fire, with the overstory being completely killed. Dense basal regeneration of velvet ash is occurring, but live vegetation is only 2 m in height. The southern half of the site is characterized by a

very dense velvet ash stand 8–9 m in height with no understory and ≥80% canopy closure. The extreme southern end of this site was also damaged in the 2010 fire with most of the trees consumed and only grass growing under the snags. Surface water was present throughout the survey season in the form of a flowing stream near the southern edge of the site. Soils were saturated in May with some standing water, but by June interior soils were completely dry.

We detected two breeding flycatchers and three individuals for which residency could not be determined. Due to flycatcher occupancy, this site was not formally surveyed. A cowbird was detected during one nest monitoring visit. No evidence of livestock was observed.

YELLOW-BILLED CUCKOO SURVEYS

No Yellow-billed Cuckoo surveys were conducted at Warm Springs in 2011 due to lack of suitable habitat.

DISCUSSION

The six Reclamation study areas occupied in 2011 by breeding flycatchers (Pahranagat NWR, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams River NWR) consistently held resident and breeding flycatchers in previous years (McKernan and Braden 2002; McLeod et al. 2008a; McLeod and Koronkiewicz 2009, 2010; McLeod and Pellegrini 2011; details of residency and breeding in 2011 are presented in Chapters 3 and 4 of this document). In 2009 and 2010, breeding flycatchers were recorded along Beaver Dam Wash at Littlefield (Littlefield Poles) for the first time since 2004. Vegetation at Littlefield Poles was scoured during floods in December 2010, and the hydrology was altered so that no surface water was present at the site during visits in May and June. Surveys were discontinued at the site after the visit in June because of these changes. No flycatchers were recorded at the site in 2011.

A single pair of breeding flycatchers was detected at a new site in 2011. Along the Bill Williams River, breeding flycatchers were detected at Cougar Point, which had not previously been surveyed. The site consists of young, even-aged vegetation that likely only recently reached sufficient size to be suitable flycatcher breeding habitat.

Hydrologic conditions at Mesquite West in May and early June 2011 were similar to those observed in all prior years except 2009. In 2009, the site was largely dry, and premature leaf abscission was observed as early as May. In 2011, the site was wet through the beginning of the breeding season In mid-June, earthwork at the inflow to the site diverted water along the edge of the site and into the Virgin River. Although the site became dry, the canopy remained largely intact with only a minor amount of leaf abscission detected in August. Despite the presence of wet conditions in early 2011, the number of resident flycatchers (11) detected at Mesquite West in 2011 was lower than the numbers detected in previous years (25, 25, 24, 20, and 16 in 2006 through 2010, respectively). The decline in flycatcher numbers between 2009 and 2010 was likely influenced by poor nest success and poor habitat conditions in 2009 (McLeod and Pellegrini 2011). Reasons for the continued decline remain undetermined, but habitat suitability in the western portion of Mesquite West, which was not occupied in 2011, may be influenced by the defoliation of tamarisk.

Marsh elevations at Topock were lower than in any year since 2005. The number of resident adults detected at Topock continued to decline, with 5 resident adults detected in 2011, versus 36, 29, 18, 20, 14, and 11 detected in each year in 2005 through 2010, respectively. Changes over the years in the timing and magnitude of fluctuations in marsh levels may have contributed to the decline in the Topock flycatcher population (see Chapter 8). We continued our efforts to locate all potentially suitable willow

flycatcher habitat at Topock Marsh. We revisited two sites that were visited briefly in 2010; one site was surveyed regularly, and visits to the other site were discontinued because of lack of suitable habitat.

Tamarisk beetles were present at both Mesquite and Mormon Mesa in 2011. Extensive defoliation was noted in the vicinity of the Mesquite sites in June, but the areas currently occupied by willow flycatchers are primarily native, and defoliation did not have any noticeable effect on breeding. Defoliation was noted in the Mormon Mesa study area at all sites starting in July, with extensive defoliation noted by late July. Roughly half of the nests in Mormon Mesa are located in primarily native stands. The remaining nests are located in either mixed stands with a primarily native canopy, or in primarily non-native vegetation. Defoliation from tamarisk beetle activity therefore potentially affected only some of the nest stands at Mormon Mesa. In addition, the majority of flycatcher nesting attempts had either fledged or failed by the time defoliation became widespread, and there was no evidence that flycatcher nesting was affected by defoliation. Defoliation will presumably occur earlier in the year in 2012 at the Mormon Mesa sites now that tamarisk beetles are established in the area and thus may have greater effects on flycatcher nesting next year. Tamarisk beetles were noted as far downstream on the Virgin River as Lake Mead by the end of August, and defoliation was also observed on the Muddy River as far downstream as Overton and as far upstream as Warm Springs. The Muddy River study area may be affected by tamarisk beetles in 2012.

Although 154 flycatcher detections were recorded at sites surveyed south of the Bill Williams, monitoring results and behavioral observations (lack of territorial, aggressive behaviors exhibited toward conspecific broadcasts) at these sites suggest these flycatchers were not resident or breeding individuals but migrants. These results are consistent with those recorded in 2003–2010 (McLeod et al. 2008a; McLeod and Koronkiewicz 2009, 2010; McLeod and Pellegrini 2011). Banding studies in the Yuma area completed in 2003–2007 also suggested that willow flycatchers detected in mid-June were migrants (McLeod et al. 2008a). Migrant willow flycatchers along the lower Colorado River could belong to one of several subspecies (*E. t. extimus*, *E. t. adastus*, or *E. t. brewsteri*), and unless an individual is banded, it is impossible to determine in the field whether a migrant is *E. t. extimus* or one of the other two subspecies. A model based on plumage color variation predicted that approximately half of 96 willow flycatchers captured in the Yuma area in mid-June in 2004–2007 were *E. t. extimus* (Paxton et al. 2010), indicating that the southwestern subspecies does use the lower Colorado River as a migration corridor. In addition, two flycatchers banded at breeding sites monitored as part of the lower Colorado River study have been detected at sites south of the Bill Williams. Both individuals were detected for only one day and did not exhibit territorial behavior, suggesting they were migrants. The first individual was detected along the Gila River in Yuma in May 2005. It was identified by the presence of a single anodized federal band as having been banded as a nestling at one of the Reclamation study areas in either 2003 or 2004. In June 2011, a fully banded flycatcher was detected in PVER 2, one of the Reclamation habitat creation sites along the LCR. While the identity of the individual could not be confirmed by repeated observations, it was very likely banded in southern Nevada. This is the first confirmed sighting of a Southwestern Willow Flycatcher in one of the habitat creation sites south of the Bill Williams. Although the bird was likely a migrant, this detection demonstrates the importance of the habitat creation sites as stopover habitat for migrating Southwestern Willow Flycatchers. Flycatchers from breeding areas along the lower Colorado River and its tributaries may also provide a potential source population for the colonization of habitat creation sites (see Discussion in Chapter 3).

Chapter 3

COLOR-BANDING AND RESIGHTING

INTRODUCTION

Long-term monitoring of willow flycatchers of known identity, sex, and age is the only effective way to determine demographic life history parameters such as annual survivorship of adults and young, site fidelity, seasonal and between-year movements, and population structure. Thus, as an integral part of our studies, we captured and uniquely color-banded as many willow flycatchers as possible, allowing field personnel to resight individuals throughout the breeding season, as well as in subsequent years. Resighting consisted of using binoculars to determine the identity of a color-banded flycatcher by observing, from a distance, the unique color combination on its legs. This allowed field personnel to detect and monitor individuals without recapturing each bird. This was our ninth consecutive year of color-banding studies and builds upon color-banding initiated at these sites in 1997 (McKernan and Braden 1998).

METHODS

Color-Banding

From early May through mid-August, we captured, uniquely color-banded, and subsequently monitored adult and nestling willow flycatchers at all study areas where resident willow flycatchers were detected. The color-banding effort also included Key Pittman Wildlife Management Area, River Ranch, and Warm Springs Natural Area in Nevada (in cooperation with Nevada Department of Wildlife) and opportunistic banding in St. George, Utah (in cooperation with Utah Division of Wildlife Resources).

Adult flycatchers were captured with mist-nets, which provide the most effective technique for live-capture of adult songbirds (Ralph et al. 1993). We used a targeted capture technique (per Sogge et al. 2001), whereby a variety of conspecific vocalizations were broadcast from a CD player and remote speakers to lure territorial flycatchers into the nets. In addition, we used “passive netting,” whereby several mist-nets were erected and periodically checked, with no broadcast of conspecific vocalizations. We banded each adult willow flycatcher with a single, numbered U.S. federal aluminum band on one leg and a colored metal band on the other. We coordinated all color combinations with the Federal Bird Banding Laboratory and all other Southwestern Willow Flycatcher banding projects to minimize duplication of color combinations. For each color-banded bird recaptured, we visually inspected the legs and noted any evidence of irritation or injury that may be related to the presence of leg bands.

Nestlings were banded at 8 to 10 days of age, when they were large enough to retain the leg bands, yet young enough that they would not prematurely fledge from the nest (Whitfield 1990, Paxton et al. 1997). Nestlings were banded only when the location of the nest was such that nest access and removal/replacement of the nestlings would not endanger the nest, nest plant, or nestlings. Nestlings were also banded with a single, numbered federal band on one leg and a metal color-band on the other leg. Prior to 2008, we banded each nestling only with a single federal band, identifying it as a returning nestling in the event it returned in a subsequent year.

For each captured adult willow flycatcher, we recorded morphological measurements, including culmen, tail, wing, fat level, and molt onto standardized data forms (Appendix A). Sex was determined based on the presence of a cloacal protuberance in males or brood patch and/or egg(s) in the oviduct for females. Captured flycatchers lacking breeding characteristics and not observed engaging in male advertising song (see below) were sexed as unknown. Flycatchers with retained primary, secondary, and/or primary covert feathers (multiple aged remiges) were aged as second year adults, and those without (uniformly aged remiges) were aged as after second year (per Kenwood and Paxton 2001 and Koronkiewicz et al. 2002). Individuals in juvenile plumage (unworn flight feathers and body plumage with broad, buff-colored wing bars and fleshy gape) were aged as hatch year.

Resighting

We determined the identity of a color-banded flycatcher by observing with binoculars, from a distance, the unique color combination on its legs. Typically, territories and active nests were focal areas for resighting, but entire sites were surveyed. Field personnel typically spent the early part of each morning color-banding, and directed their efforts to resighting as daylight increased and flycatchers became more difficult to capture. All banding, monitoring, and survey field personnel coordinated resighting efforts and recorded observations of color-banded and unbanded flycatchers onto standardized data forms (Appendix A). For resighted flycatchers (i.e., ones for which at least one leg was seen clearly enough to determine the presence or absence of a band), we recorded color-band combinations, territory number, site, standardized confidence levels of the resight, and behavioral observations. Willow flycatchers for which detections spanned one week or longer were considered resident at a site, regardless of the portion of the breeding season in which the bird was observed or whether a possible mate was observed. Flycatchers observed engaging in breeding behaviors (e.g., carrying nest material) were also considered resident regardless of the period of time over which they were observed. Flycatchers observed engaging in lengthy, primary song from high perches (male advertising song) were sexed as male, and flycatchers observed carrying nest material or constructing or incubating a nest were sexed as female. Flycatchers not observed engaging in one of these diagnostic activities were sexed as unknown.

Inactive territories were visited at least three times (each visit four days apart) before territory visits stopped. All territories were assigned a unique alphanumeric code and were plotted onto high-resolution aerial photographs, thus producing a spatial representation of the flycatcher population at each study location. If multiple females were paired with a single male, each female received a unique territory number. Flycatchers were determined to be unpaired if none of the following breeding behaviors were observed: presence of another unchallenged flycatcher in the immediate vicinity, counter calling (*whitts*) with a nearby flycatcher, interaction twitter calls (*churr/kitters*) with a nearby flycatcher, a flycatcher in the immediate vicinity carrying nesting material, a flycatcher in the immediate vicinity carrying food or fecal sac, or adult flycatchers feeding young (per Sogge et al. 1997).

Unbanded flycatchers could not be identified to individual, but an unbanded flycatcher detected in a given location on multiple, consecutive visits was assumed to be the same individual. If an unbanded flycatcher or a flycatcher whose legs were not observed was detected at a given location on multiple visits but one or more intervening visits failed to detect a flycatcher, the detections were considered to be different individuals in the absence of behavioral observations indicating the flycatcher was actively defending a territory or was a member of a breeding pair.

RESULTS

Reclamation Study Areas

Color-Banding and Resighting – Field personnel color-banded 15 new adult flycatchers and recaptured 11 individuals previously captured as adults. An additional 31 adults were identified to individual via resighting, while 3 individuals were resighted but did not have their color combinations confirmed. Of the 31 adults that were resighted and identified, one was identified for the first time since it was banded as a nestling. We identified two additional individuals as returning nestlings by the presence of a single federal band, with one (50%) identified to individual via recapture. We recaptured two additional returning nestlings with full color combinations. Thirty adult flycatchers remained unbanded, and banding status was undetermined (i.e., we were unable to determine if these individuals were banded) for 30 adults. Overall, 52% of the adult flycatchers detected at the monitoring sites were known to be color-banded by the end of the breeding season (Table 3.1). We banded 40 nestlings from 17 nests. Of the 40 nestlings banded, 5 were known or suspected to have died before fledging. We resighted an additional 10 unbanded fledglings from six nests; one fledgling was captured and banded. For details on all banded flycatchers detected at the study areas from 2003 to 2011, see Appendix E.

Site-by-Site Color-Banding and Resighting

Pahranagat – We detected 14 resident, adult willow flycatchers from 10 territories at Pahranagat. In addition to resident adults, we detected seven individuals for which residency and/or breeding status could not be confirmed (Table 3.2). Of the 10 territories recorded at Pahranagat, 6 consisted of breeding pairs, and 4 consisted of unpaired males. Of the breeding individuals, one male was polygynous with three females. One resident female moved from her territory in Pahranagat North and was resighted at Pahranagat West along with three banded fledges.

Field personnel captured and color-banded four new adults and recaptured three flycatchers previously captured as adults. We resighted and identified an additional 10 adults. Three adults remained unbanded. Of the resighted adults, one was originally banded as a nestling in 2010 (see Table 3.8 for juvenile dispersal data). The color combination could not be determined for one adult. We banded 11 nestlings from four nests. We resighted seven unbanded fledglings from three additional nests; one fledgling was captured and banded.

Mesquite – We detected 14 resident, adult willow flycatchers from eight territories at Mesquite. Of the eight territories recorded at Mesquite, seven consisted of paired individuals and one consisted of an unpaired male (Table 3.2). Of the breeding individuals, two males were each polygynous with two females. The male at one territory was displaced by another male that moved from Muddy River (Table 3.9).

Field personnel captured and color-banded three new adults and confirmed the identities of an additional six adults via resighting. Three adults remained unbanded, and band status could not be determined for two adults. We banded five nestlings from two nests.

Mormon Mesa – We detected 23 resident, adult willow flycatchers from 14 territories at Mormon Mesa. In addition to resident adults, we detected three individuals for which residency could not be confirmed (Table 3.2). Of the 14 territories recorded at Mormon Mesa, 13 consisted of breeding individuals and 1 consisted of an unpaired male. One breeding male moved from Muddy River, and one male for which residency could not be confirmed moved from Mesquite West (Table 3.9). One female mated

consecutively with two males and four males were polygynous, one with three females and three with two females.

Field personnel captured and color-banded one new adult and recaptured five flycatchers previously captured as adults. We resighted and identified nine additional adults. We captured one returning nestling originally banded as a juvenile in 2007 (see Table 3.8) and resighted one returning nestling with a single federal band that we were unable to recapture. Eight adults remained unbanded, and band combination could not be confirmed for one adult. We banded 16 nestlings, two of which were suspected to have died before fledging, from seven nests and resighted three unbanded fledglings from three nests.

Muddy River – We detected 13 resident, adult willow flycatchers from eight territories at Muddy River. In addition to resident adults, we detected three individuals for which residency could not be confirmed. Of the eight territories recorded, five consisted of breeding pairs and three consisted of unpaired males (Table 3.2). One breeding male moved to Mormon Mesa and one unpaired male moved to Mesquite (Table 3.9).

Field personnel captured and color-banded three new adults and recaptured two flycatchers previously captured as adults. We recaptured two returning nestlings; one was originally banded in 2009 and the other in 2010 (see Table 3.8). We resighted and identified four other adults. Four adults remained unbanded, and band status could not be confirmed for one adult. We banded four nestlings from two nests; three of these nestlings died before fledging.

Topock – We detected five resident, adult willow flycatchers from five territories at Topock. In addition to resident adults, we detected 28 individuals for which residency could not be confirmed (Table 3.2). Of the five territories recorded at Topock, one consisted of a breeding pair and four consisted of unpaired males. One of the unpaired males established a territory at Platform and then moved to The Wallows and established a second territory.

Field personnel captured and color-banded two new adults and recaptured one flycatcher originally captured as an adult. We resighted and identified one other banded adult. Nine adults remained unbanded, and the band status of 19 individuals could not be determined. The color combination of one banded adult could not be confirmed.

Bill Williams – We detected eight resident willow flycatchers from five territories at Bill Williams. In addition to resident adults, we detected nine individuals for which residency could not be determined (Table 3.2). Of the five territories recorded at Bill Williams, four consisted of breeding individuals and one consisted of an unpaired male. One male was polygynous with two females. At one breeding territory, personnel from an unrelated field crew reported a singing male, but only the female was detected during nest monitoring visits.

Field personnel captured and color-banded two new adults. We resighted and identified four returning banded adults. Three adults remained unbanded, and band status could not be determined for eight adults. We banded four nestlings from two nests.

Table 3.1. Willow Flycatchers Detected at Reclamation Study Areas Where Resident Flycatchers Were Observed during the 2011 Breeding Season*

Study Area	Site	Adults									Nestlings Banded (# nests)	Fledglings Captured	% of All Adults Banded

* Individuals are identified as new captures (previously unbanded), recaptures of previously banded birds, resightings of previously banded birds for which band combinations were confirmed, birds known to be unbanded, birds for which band status could not be determined, and resighting of previously banded birds for which band combinations were undetermined. Included are total numbers of adults detected and percent of all adults banded. For breeding and/or residency status of adults see Table 3.2.

[1] One individual moved from North to West and is tallied only once in the total.

[2] Three HY individuals moved from North to West. These individuals were resighted, not captured, at West and are not tallied in the total.

[3] One individual moved from Muddy River Overton WMA to Mesquite Hafen Lane and is tallied only once in the total.

[4] One individual moved from Mesquite West to Mormon Mesa Virgin River #1 South and is tallied only once in the total.

[5] One individual moved from Muddy River Overton WMA to Mormon Mesa Virgin River #1 South and is tallied only once in the total.

[6] Returning nestling.

[7] Two nestlings suspected to have died before fledging.

[8] Three nestlings died before fledging.

[9] One individual moved from 800M to Pipes #3 and is tallied only once in the total.

[10] One individual moved from Platform to The Wallows and is tallied only once in the total.

[11] Not a formal survey site. Flycatchers detected en route.

[1] PAHR = Pahranagat NWR, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR.

[2] N/A = not applicable, INA = information not available.

[3] **Color-band codes**: EE = electric yellow federal band, PU = pumpkin federal band, Bs = blue federal band, XX = standard silver federal band, TQ = turquoise federal band, (M) = metal pin striped band, UB = unbanded, R = red, O = orange, Y = yellow, G = green, D = dark blue, B = light blue, V = violet, W = white, K = black, Z = gold, banded = bird was banded but combination could not be determined, undetermined = presence of bands could not be determined. Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band; color-band designations for right and left legs are separated with a colon.

[4] Old combination included only if rebanded in 2011.

[5] **Age in 2011**: L = nestling, HY = hatch year, SY = 2 years, AHY = 2 years or older, 3Y = 3 years, A3Y = 3 years or older, 4Y = 4 years, A4Y = 4 years or older, etc.

[6] **Sex codes**: M = male, F = female, U = unknown.

[7] **Territory or Location code**: Number without an alpha code indicates a flycatcher pair, T = territorial individual detected for at least 7 days, F = individual detected for less than 7 days. Number indicates unique location.

[8] **Observation status codes**: N = new capture, R = recapture followed by date recaptured, RS = resight.

[9] Original federal band number 2390-92434.

[10] Original federal band number 2430-61167. Individual resighted at the beginning of the season with XX:KW(M) with an injured left leg but subsequently lost the left foot and federal band.

[11] Further review of data suggests this individual likely present at MUDD 9 Jul–3 Aug 2010 and erroneously reported (McLeod and Pellegrini 2011) as DR(M):TQ.

AR064176

NDOW Study Areas

Color-Banding and Resighting – Field personnel color-banded 13 new adult flycatchers and recaptured 3 individuals previously captured as adults. An additional 25 adults were identified to individual via resighting, while 2 individuals were resighted but did not have color combinations confirmed. We recaptured one individual identified as a returning nestling by the presence of a single federal band from 2007. Three additional adults were captured with full color combinations and identified as returning nestlings from 2009 or 2010 (Table 3.8). Five adult flycatchers remained unbanded, and banding status was undetermined (i.e., we were unable to determine if these individuals were banded) for one adult. Overall, 89% of the adult flycatchers detected at the monitoring sites were known to be color-banded by the end of the breeding season (Table 3.3). We banded 34 nestlings from 13 nests. Of the 34 nestlings banded, 3 were suspected to have died before fledging. For details on all banded flycatchers detected at the study areas from 2003 to 2011, see Appendix E.

Site-by-Site Color-Banding and Resighting

Key Pittman Wildlife Management Area – We detected 34 resident willow flycatchers from 19 territories at Key Pittman Wildlife Management Area. In addition to resident adults, we detected eight individuals for which residency and/or breeding status could not be determined (Table 3.4). Of the 19 territories at Key Pittman, 18 consisted of breeding individuals and 1 consisted of an unpaired male. Three males were each polygynous with two females.

Field personnel captured and color-banded 11 new adults and recaptured five flycatchers previously seen as adults (Table 3.4). We resighted and identified 20 additional adults; 5 of these individuals were detected for the first time since they were banded as nestlings in 2010 (see Table 3.8). We captured two returning nestlings originally banded as juveniles in 2007 and 2009. Two adults remained unbanded, and color combinations could not be confirmed for two adults. We banded 31 nestlings from 12 nests; we suspect three of these nestlings from two nests died before fledging. We resighted four unbanded fledglings from three additional nests.

River Ranch – We detected seven resident willow flycatchers from four territories at River Ranch. In addition to resident adults, we detected two individuals for whom residency and/or breeding status could not be determined (Table 3.4). Of the four territories at River Ranch, two consisted of breeding individuals, one consisted of a pair with no documented breeding activity, and one consisted of an unpaired male.

Field personnel captured and color-banded two new adult flycatchers. We resighted and identified six additional adults, five of which were banded as nestlings in 2010 (Table 3.8). One adult remained unbanded.

Warm Springs Natural Area – We detected two resident willow flycatchers from one territory at Warm Springs Natural Area. In addition to resident adults, we detected three individuals for whom residency and/or breeding status could not be determined (Table 3.4). The single territory at Warm Springs consisted of breeding individuals.

Field personnel did not capture or recapture any adult flycatchers. We resighted and identified two adults. Two adults remained unbanded, and the presence of bands could not be confirmed for one adult. We banded three nestlings from one nest.

* Individuals are identified as new captures (previously unbanded), recaptures of previously banded birds, resightings of previously banded birds for which band combinations were confirmed, birds known to be unbanded, birds for which band status could not be determined, and resighting of previously banded birds for which band combinations were undetermined. Included are total numbers of adults detected and percent of all adults banded. For breeding and/or residency status of adults see Table 3.4.

[1] One individual moved from River Ranch West Side to Key Pittman WMA Patch 0 and is tallied only once in the total.

[2] Nestling suspected to have died in nest.

[3] One individual resighted in Key Pittman Patch 3 was recaptured in Patch 4, and is tallied only once in the total.

[4] One individual moved from River Ranch East Side to Key Pittman WMA Patch 4 and is only tallied once in the total.

[5] One individual moved from River Ranch West Side to Key Pittman WMA Patch 10.5 and is only tallied once in the total. This individual was resighted in Patch 10.5 and later recaptured in Patch 4, and is tallied only once in the total.

[6] One individual was detected in Patch 11 and Patch 6 and is tallied only once in the total.

[7] One individual recaptured in Patch 10.5 and Patch 12 and is tallied only once in the total.

[8] Two nestlings suspected to have died before fledging in one nest.

[9] Not a formal survey area. Individual detected in passing between Patches 5 and 6 on fence-line that runs along highway.

[1] KEPI = Key Pittman WMA; RIRA = River Ranch; WMSP = Warm Springs Natural Area.

[2] N/A = not applicable, INA = information not available.

[3] **Color-band codes**: EE = electric yellow federal band, PU = pumpkin federal band, Bs = blue federal band, XX = standard silver federal band, TQ = turquoise federal band, (M) = metal pin striped band, UB = unbanded, R = red, O = orange, Y = yellow, G = green, D = dark blue, B = light blue, V = violet, W = white, K = black, Z = gold, banded = bird was banded but combination could not be determined, undetermined = presence of bands could not be determined. Color combinations are read as the bird's left leg and right leg, top to bottom; two or three letters designate every band; color-band designations for right and left legs are separated with a colon.

[4] Old combination included only if rebanded in 2011.

[5] **Age in 2011**: L = nestling, HY = hatch year, SY = 2 years, AHY = 2 years or older, 3Y = 3 years, A3Y = 3 years or older, 4Y = 4 years, A4Y = 4 years or older, etc.

[6] **Sex codes**: M = male, F = female, U = unknown.

[7] **Territory or Location code**: Number without an alpha code indicates a flycatcher pair, T = territorial individual detected for at least 7 days, F = individual detected for less than 7 days. Number indicates unique location.

[8] **Observation status codes**: N = new capture, R = recapture followed by date recaptured, RS = resight.

[9] Further review of data suggests this individual likely present at KEPI during the 2010 breeding season, but this cannot be confirmed.

[10] Original federal band number 2430-61134.

AR064182

Non-Monitoring Sites

This study area was monitored by another agency, and here we report only banded flycatchers that were captured or resighted. Unbanded individuals or those with unknown band status are not included.

St. George – Field personnel captured and color-banded two new adults and recaptured one individual previously captured as an adult (Table 3.5). We banded one nestling. Personnel from Utah Division of Wildlife Resources resighted and identified an additional four adult flycatchers. Two more banded adults were resighted, but their identities could not be confirmed.

Adult Between-Year Return and Dispersal

In 2010 we individually identified 96 adult, resident willow flycatchers at all monitored study areas, of which 55 (57%) were detected in 2011 (Table 3.6). Of the returning resident adults, five (9%) were detected at a different study area than where they were last detected in 2010 (Table 3.7). One adult flycatcher that was detected in 2010 at a site monitored by NDOW was detected at a different study area in 2011. Two additional flycatchers that were last detected in 2008 or 2009 exhibited between-year movement in 2011. The median dispersal distance for all returning adult flycatchers exhibiting between-year movements in 2011 was 86.8 km (min = 11.9 km, max = 203.1 km).

[5] Further review of data suggests this individual moved from TOPO to MUDD during the 2010 breeding season but this cannot be confirmed.

Juvenile Between-Year Return and Dispersal

In 2010, we banded 52 nestlings at the Reclamation study areas. One of these nestlings was known to have died before fledging. Of the remaining 51 juveniles, 2 (4%) were identified in 2011. Two individuals originally banded as nestlings in 2007 and two individuals originally banded as nestlings in 2009 were identified for the first time in 2011 (Table 3.8). In 2010, we banded an additional 41 nestlings at the NDOW study areas. Five of these nestlings were known to have died before fledging. Of the remaining 36 juveniles, 9 (25%) were identified in 2011 (Table 3.8). No additional nestlings banded in prior years at NDOW sites were identified. Of the 16 returning nestlings identified in 2010, 12 (75%) dispersed away from their natal study area. The median dispersal distance for all returning juvenile flycatchers in 2011 was 12.8 km (min = 0.03 km, max = 138.0 km).

One additional returning nestling from 2003–2007 was resighted in 2011 at Mormon Mesa, but the identity of this individual was undetermined because we were unable to recapture it.

Within-Year, Between-Study Area Movements

We detected seven within-year, between-study area movements in 2011 (Table 3.9). Three individuals moved from River Ranch to Key Pittman WMA. One male held a territory in River Ranch West Side (23 June – 1 July), was detected on 24 July at Key Pittman Patch 10.5, and recaptured passively on 27 July in Patch 4. The female from the same territory in River Ranch West Side moved after a failed nesting attempt (23 – 27 June) to Key Pittman Patch 0 where she had another nesting attempt of unknown fate (8 July – 4 August). Another individual, likely a male, was present in River Ranch East Side (15 June – 25 July) and was recaptured passively at Key Pittman Patch 4 on 27 July. A male at Pahranagat North was detected 17 – 19 June and moved to River Ranch West Side where he held a territory from 23 June to 13 July. One male held a territory at Mesquite West (17 May – 19 July) and was recaptured passively on 24 July in Mormon Mesa Virgin River #1 South. Two males moved from Muddy River Overton WMA after holding territories. One male held his territory from 17 May to 17 July and was then detected at Mesquite Hafen Lane from 21 to 23 July. The other male held his territory from 17 June to 17 July and then moved to Mormon Mesa Virgin River #1 South where he was detected from 2 to 17 August.

DISCUSSION

Color-Banding Effort

Overall, 52% of the adult flycatchers detected at the monitoring sites during 2011 were banded by the end of the breeding season. This compares to 55, 57, 75, 70, 73, 69, 67 and 66% in 2003–2010, respectively. Unbanded willow flycatchers with an undetermined residency status are included in calculating these percentages; therefore, in most cases, these numbers under-represent the actual proportion of resident banded flycatchers at a given site. Differences between study areas in the percentage of banded individuals are related to vegetation density and overall structure, which affect our ability to erect mist-nets in the habitat, and the percentage of adults that are residents. Topock Marsh typically has the lowest percentage of color-banded flycatchers because dense vegetation limits the number and size of possible net locations and because, particularly in recent years, the number of resident adults is low in comparison to the total number of flycatchers detected.

Prior to 2008, we banded all nestlings with a single anodized federal band, identifying the bird as a returning nestling in the event it was sighted in a subsequent year. The individual would then have to be recaptured to determine its individual identity and to apply a unique color combination so the bird could be individually identified via resighting. The rationale for banding nestlings with a single anodized band was that the majority of nestlings do not return in subsequent years, resulting in the loss of a large number of unique color combinations. To eliminate the need to recapture returning nestlings, in 2008–2011 we applied unique color combinations to all nestlings. The use of full color combinations on nestlings in 2008–2010 has greatly reduced the number of adults with single federal bands, with only three detected across all study areas in 2011. Banding nestlings with full color combinations also allows us to record juvenile dispersal movements that might otherwise go undetected.

Adult and Juvenile Between-Year Dispersal

Resident adults detected at Topock have historically shown very high site fidelity. Until 2010, when we documented between-year movement of an adult male from Topock to Warm Springs, no between-year movements of resident Topock adults to another study area had been detected. In 2011, two additional between-year movements of resident Topock adults to other study areas were documented. One was a

breeding female identified in Mormon Mesa who had last been identified in 2010 as a breeding female in Topock. The other was a breeding male from Muddy River who was last documented in 2010 as a resident, unpaired male in Topock. These two movements provide further evidence that individuals who do not return to Topock after being documented in a given year may be moving to other locations. When an individual is not identified in a given year, there is no way to distinguish between going undetected, mortality, or emigration from the study area. Documenting emigration allows for an estimation of emigration rates, thereby improving the accuracy of survival estimates. It is possible that there have been movements of resident, unbanded Topock adults to other monitored study areas, but there would be no way to detect these movements. Furthermore, the movement of the female to Mormon Mesa may also be indicative of the poor habitat conditions present in Topock in 2011. Females who breed successfully in a given year typically demonstrate high site fidelity the following year. This female successfully fledged two nestlings in 2010 and was not detected in Topock in 2011.

Adult and juvenile dispersal data for the 2011 field season show overall high site fidelity exhibited by adult flycatchers and lower natal site fidelity exhibited by juveniles, with juveniles dispersing among study areas. These dispersal data are consistent with the patterns observed in the LCR region from 1998 to 2011, over which period 90% of adult returns were to the same study area, while only 48% of all juvenile returns were to the natal study area (McKernan and Braden unpubl. data; McLeod et al. 2008a; McLeod and Koronkiewicz 2009, 2010; McLeod and Pellegrini 2011). These dispersal data are also consistent with range-wide data (Paxton et al. 2007), with adult flycatchers exhibiting high site fidelity to breeding areas. Juvenile dispersal within the Virgin/lower Colorado River population(s) is largely limited to this region, and while reciprocal juvenile movements among geographically isolated flycatcher populations of the greater Southwest do occur, they are rare. Only three instances of willow flycatcher immigration from sites outside the Virgin/lower Colorado River region have been recorded since 1997 (McKernan and Braden unpubl. data, McLeod et al. 2008a), with two males originally banded as nestlings in 2003 at Roosevelt Lake recaptured in 2005 at Muddy River and Topock, and one male banded as a nestling in 1999 at Roosevelt Lake recaptured in 2002 in Grand Canyon. Although movements of this magnitude are infrequent, other instances of dispersal distances greater than 140 km have been reported for the Southwestern Willow Flycatcher (Paxton et al. 2007) and have been noted within the Virgin/lower Colorado River population (McLeod et al. 2008a, McLeod and Koronkiewicz 2010, McLeod and Pellegrini 2011). Banding studies at Roosevelt Lake and along the San Pedro River were discontinued after 2005, so immigration of juveniles produced in those areas after 2005 would have gone undetected.

The observed dispersal patterns fit well with the tenets of contemporary metapopulation theory (Hanski and Simberloff 1997), suggesting the Virgin/lower Colorado River population may be a panmictic sub-population of a greater metapopulation. Occasional juvenile dispersal between sub-populations is likely an important population variable in terms of gene flow, with movements contributing to an understanding of the observed patterns of high genetic diversity within and low genetic isolation among Southwestern Willow Flycatcher populations (Busch et al. 2000). Dispersal by juveniles or adults is required for the colonization of new breeding sites, and long-distance movements will be required if newly established Reclamation habitat creation sites are to be colonized. The closest known breeding sites are at Bill Williams River NWR and Topock Marsh, approximately 75–150 km from the PVER and CVCA habitat creation sites (see Chapter 2). The habitat creation sites could also be colonized by individuals from more distant breeding areas, such as those along the Virgin River. Although such long-distance movements are relatively infrequent, two adult movements between the lower Colorado and the Virgin River were documented in 2011, and multiple instances of adult and juvenile dispersal between the Virgin River and Topock Marsh and Bill Williams River NWR have been documented in recent years (McLeod et al. 2008b; McLeod and Koronkiewicz 2009, 2010; McLeod and Pellegrini 2011). Physical connectivity of riparian habitats within the greater landscape is crucial in enabling these long-distance movements. Without adequate stop-over habitats and foraging areas, flycatchers attempting long-distance movements are more likely to be exposed to adverse environmental conditions.

Within-year, Between Study Area Movement

Within-year, between study area movements typically occur at low rates in any given year. In 2003–2010, we detected between zero and four (median = 1.5) movements per year. In 2011, we documented the largest number of individuals (seven) moving between study areas within a given year. The increase in the number of documented movements may have been affected by the addition in 2011 of River Ranch to the monitored study areas. Movements to and from River Ranch accounted for four (57%) of the seven movements. One additional within-year movement, which would otherwise likely have gone undetected, was detected via passive netting. Thus, the detection of an unusually high number of within-year movements in 2011 is not necessarily indicative of there being more movements, but rather that we were better able to detect them.

The movement of three of the seven resident or paired adults at River Ranch to another study area is suggestive of poor habitat quality at River Ranch. In addition, eight of the nine individuals detected at River Ranch were known to be second-year individuals (age of the ninth individual was unknown). A high proportion of second-year birds could also be indicative of poor habitat quality. This pattern is seen in multiple species where the best habitat is typically occupied by older individuals, who may be more competitive or arrive sooner on the breeding grounds, leaving habitat of lesser quality for younger birds (Hill 1988, Holmes et al. 1996). Higher proportions of second-year birds also tend to be seen in young, newly developed habitat, such as that seen in the lower Grand Canyon in 2006–2008, possibly as a result of dispersal and colonization (McLeod et al. 2007, McLeod et al. 2008b, McLeod and Koronkiewicz 2009). However, the habitat at River Ranch has been established for several years (C. Tomlinson, NDOW, pers. comm.), and the high proportion of second-year birds is more likely due to habitat quality than stand age.

Adult and Juvenile Survivorship

Annual survivorship is defined as the number of individuals that survive from one year to the next, and accurate estimates depend on year-to-year detection of uniquely marked birds. Fifty-seven percent of the adult, resident willow flycatchers identified in 2010 were detected again in 2011, while of the 87 juveniles banded in 2010, only 11 (13%) were identified in 2011. Thus, minimum estimated adult and juvenile survival from 2010 to 2011 at all monitored sites was 57 and 13%, respectively. These simple annual percent survivorship calculations assume that all living flycatchers are detected in a given year, and individuals not detected are assumed to have died, unless detected elsewhere. To provide more robust estimates of annual survival, demographic data acquired from 2003 to 2012 will be combined with data collected during 1997–2002. Survival and detection probabilities will be estimated using program MARK (White and Burnham 1999) and presented in a summary report in 2012.

Chapter 4

NEST MONITORING

INTRODUCTION

Documentation of nest success and productivity is critical to understanding local population status and demographic patterns of the Southwestern Willow Flycatcher. In 2011, at all sites where willow flycatcher breeding activity was suspected, we conducted intensive nest searches and nest monitoring. Specific objectives of nest monitoring included identifying breeding individuals (see Chapter 3, Color-banding and Resighting), calculating nest success and failure, documenting causes of nest failure (e.g., abandonment, desertion, depredation, and brood parasitism), and calculating nest productivity. Nest monitoring results from 2011 were compared with those at the study areas from 1996 to 2010 (Braden and McKernan unpubl. data; McLeod et al. 2008a; McLeod and Koronkiewicz 2009, 2010; McLeod and Pellegrini 2011). Although aspects of willow flycatcher breeding ecology can vary widely across its broad geographical and elevational ranges throughout the Southwest (Whitfield et al. 2003), we compared monitoring results with range-wide data to identify specific variables that may contribute to the characterization of flycatcher breeding ecology throughout the lower Colorado and Virgin River riparian systems.

METHODS

Upon locating territorial willow flycatchers, regardless of whether a possible mate was observed, we conducted intensive nest searches following the methods of Rourke et al. (1999). Nest monitoring followed a modification of the methods described by Rourke et al. (1999) and the Breeding Biology Research and Monitoring Database (BBIRD) protocol by Martin et al. (1997).

Nests were located primarily by observing adult flycatchers return to a nest or by systematically searching suspected nest sites. Nests were monitored every two to four days after nest building was complete and incubation was confirmed. Nests at NDOW study areas were monitored less frequently (every four days or more) because of budgetary restrictions. During incubation and after hatching, nest contents were observed directly using a telescoping mirror pole to determine nest contents and transition dates. Nest monitoring during nest building and egg laying stages was limited to reduce the chance of abandonment during these periods. To reduce the risk of depredation (Martin et al. 1997), brood parasitism by the Brown-headed Cowbird, and premature fledging of young (Rourke et al. 1999), we observed nests from a distance with binoculars once the number and age of nestlings were confirmed. If no activity was observed at a previously occupied nest, the nest was checked directly to determine nest contents and cause of failure. If no activity was observed at a nest close to or on the estimated fledge date, we conducted a systematic search of the area to locate possible fledglings.

Per instructions from Reclamation biologists, we considered a willow flycatcher nest successful only if fledglings were observed near the nest or in surrounding areas. The number of young fledged from each nest was counted based on the number of fledglings actually observed. This method of determining success differs from that recommended by some nest monitoring protocols (e.g., Martin et al. 1997, Rourke et al. 1999), which consider a nest as successful if chicks are observed in the nest within two days of the estimated fledge date. The method we follow produces a conservative estimate of both nest success rate and number of fledges.

We considered a nest to have failed if (1) the nest was abandoned prior to egg laying (abandoned); (2) the nest was deserted with flycatcher eggs or young remaining (deserted); (3) the nest was found empty or destroyed more than two days prior to the estimated fledge date (depredated); (4) nestlings died in the nest despite being tended by the adults(nestlings died in nest); or (5) the entire clutch was incubated for an excess of 20 days (infertile/addled). For nests containing flycatcher eggs, parasitism was considered the cause of nest failure if (1) cowbird young outlived any flycatcher eggs or young, or (2) the nest was parasitized during egg laying and the disappearance of flycatcher eggs coincided with the appearance of cowbird eggs.

During each nest check, we recorded date and time of the visit, observer initials, monitoring method (observation via binoculars or mirror pole), nesting stage, nest contents, and number and behavior of adults and/or fledges present onto standardized data forms (Appendix A) that included the nest or territory number and UTM coordinates. We calculated flycatcher nest success using both apparent nesting success (number of successful nests/total number of nests containing at least one flycatcher egg) and the Mayfield method (Mayfield 1961, 1975), which calculates daily nest survival to account for nests that failed before they were found. We assumed one egg was laid per day, and incubation was considered to start the day the last egg was laid (per Martin et al. 1997). The nestling period was considered to start the day the first egg hatched and end the day the first nestling fledged. If exact transition dates or dates of depredation events were unknown, we estimated the transition date as halfway between observations. For nests where fate was unknown, we used the last known date of activity to determine the number of observation days. To calculate Mayfield survival probabilities (MSP), we used the average length of each nest stage (2.14, 12.85, and 13.76 days for laying, incubation, and nestling stages, respectively) as observed in this study in 2003–2011 for nests where transition dates were known. Nest productivity was calculated as the number of young fledged per nesting attempt that produced at least one flycatcher egg. Fecundity was calculated as number of young produced per female over the breeding season. Parasitism rates were calculated as the percentage of nests with known contents that included at least one flycatcher egg and one cowbird egg.

In 2011, we attempted to addle cowbird eggs in easily accessible flycatcher nests at all study areas except Pahranagat. If the nest was accessible without a ladder, the cowbird egg was addled as soon as it was discovered. If a ladder was required, the cowbird egg was addled on the next regularly scheduled nest visit. Cowbird eggs were addled only if we could obtain a direct view of the nest contents from a secure location, either on the ground on or a ladder. We carefully removed the cowbird egg from the nest and placed it in a padded film canister. We then shook the canister vigorously for about one minute, incorporating sharp, jerky movements. The egg was then returned to the nest. The cowbird egg was not permanently removed from the nest so as not to mimic a partial depredation event, which might result in nest desertion. If a nest was found with a cowbird nestling already in the nest, or if a shaken cowbird egg still hatched, we removed the cowbird nestling from the nest.

All field personnel practiced egg addling with several button quail (*Coturnix chinensis*) eggs at the start of field season to determine how vigorously they could shake an egg without breaking it. Button quail eggs are slightly larger than cowbird eggs (19 x 25 mm vs. 16 x 21 mm) but provide a reasonable and easily available substitute. Shaken eggs were carefully opened to determine whether any damage to the internal structure of the egg was apparent. Field personnel varied in their ability to shake an egg to the point of causing internal damage without breaking the shell.

RESULTS

Reclamation Study Areas

Nest Monitoring

We documented 49 willow flycatcher nesting attempts at Pahranagat, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams; 43 of these nests were known to contain flycatcher eggs and were used in calculating nest success and productivity. Eighteen (42%) nests were successful and fledged young, and 23 (53%) failed. The fate of two nests (5%) was unknown. Nest success ranged from 0% at Topock Marsh to 100% at Pahranagat (Table 4.1). For a comparison of apparent nest success at all monitoring sites from 1997 to 2011, see Table 4.2.

Thirty-five nesting females, of which all but three were known to have produced at least one egg, were followed through all of their nesting attempts. One additional female was documented for which no nesting attempt could be confirmed. Of the 35 nesting females, 23 had one nesting attempt, 10 had two nesting attempts, and 2 had three nesting attempts. Of the 12 females with multiple nesting attempts, 9 renested after failed nests and 3 renested after a successful nest.

* Data from 1997 to 2002 are from Braden and McKernan (unpubl. data); these numbers have been verified with the raw data and may differ from those presented in earlier annual reports. Data from 2003 to 2007 are from McLeod et al. 2008a; data from 2008 are in McLeod and Koronkiewicz 2009; data from 2009 are in McLeod and Koronkiewicz 2010; data from 2010 are in McLeod and Pellegrini 2011, and data from 2011 are in this document. Total number of nests containing at least one flycatcher egg is indicated in parentheses.

[1] Study area includes the Hafen Lane, Mesquite East, Mesquite West, and Bunker Farm sites.

[2] Study area includes the Virgin River Delta at Lake Mead.

[3] Nm = study area not monitored.

[4] Nd = study area surveyed, no breeding documented.

[5] Nc = breeding confirmed, nest success not calculated.

[6] Bc = breeding confirmed, undetermined if nestlings from a single nest fledged.

[7] An additional three nests (18%) were suspected to have fledged but fledglings were not visually confirmed.

[8] Fate of one nest was unknown.

Nest Failure

Depredation was the major cause of nest failure, accounting for 52% (15 of 29) of all failed nests (Table 4.3) and 65% (15 of 23) of nests that failed after flycatcher eggs were laid. Six nesting attempts (21% of all failed nests) were abandoned prior to willow flycatcher eggs being laid, three nests (10%) were deserted, and three nests (10%) were incubated in excess of 20 days. Two nests (7%) failed because of Brown-headed Cowbird parasitism (see below for more details on parasitism).

Brood Parasitism

Seven of 37[1] nests (19%) with flycatcher eggs and known contents were brood parasitized by Brown-headed Cowbirds (Table 4.4). For nests containing flycatcher eggs, parasitism caused nest failure at two nests. In one case, the parasitism event coincided with the disappearance of all flycatcher eggs; in the other, the nest contained one cowbird nestling when it was found. No parasitized nests were known to

[1] Table 4.1 shows a total of 43 nests known to contain at least one flycatcher egg. When calculating brood parasitism rates, however, six nests whose contents could not be determined were excluded from calculations (e.g., nests that were too high to check contents to determine presence/absence of cowbird eggs or nesting attempts that were discovered late in the nesting cycle).

fledge a flycatcher, but the fate of one nest was unknown. Of the remaining four parasitized nests that contained flycatcher eggs, two were depredated and two contained addled flycatcher eggs. Brood parasitism ranged from 0 to 60% and was highest at Muddy River (see Table 4.1). In 2011, nests that contained flycatcher eggs and were brood parasitized were less likely to fledge flycatcher young than nests that were not parasitized (one-sided Fisher's exact test, $P = 0.038$).

Table 4.3. Summary of Causes of Willow Flycatcher Nest Failure at Reclamation Study Areas, 2011*

Study Area[1]	Total # Nests	All Failed Nests	Abandoned	Deserted	Depredated	Parasitized	Addled
PAHR	7	0	0	0	0	0	0

* All nesting attempts (those with and without flycatcher eggs) are included. Percentage of failed nests is shown in parentheses for each cause of failure.

[1] PAHR = Pahranagat NWR, MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, TOPO = Topock Marsh, BIWI = Bill Williams River NWR.

[2] One nest deserted after partial depredation, one deserted after 18 days incubation, one deserted during incubation with one flycatcher egg.

Table 4.4. Fates of Willow Flycatcher Nests Parasitized by Brown-headed Cowbirds, 2011*

Study Area[1]	Nest ID Code	Outcome[2]
MESQ	32A	Incubated >20 days. CE was addled and never hatched
	72B	Depredated during incubation
MOME	90A	Depredated during incubation
MUDD	3A	Fate unknown. One 14-day-old WN seen on nest rim, but fledging not confirmed. CE was addled and never hatched
	11A	3 WE disappeared and CE appeared 17 days into incubation
	18A	Incubated >20 days. CE was addled and never hatched
BIWI	33A	Nest found with one CN and no flycatcher nestlings or WE

* All nesting attempts are included.

[1] MESQ = Mesquite, MOME = Mormon Mesa, MUDD = Muddy River, BIWI = Bill Williams River NWR.

[2] WE = willow flycatcher egg, CE = cowbird egg, WN = willow flycatcher nestling, CN = cowbird nestling.

Cowbird Egg Addling

We attempted to addle cowbird eggs at three of the seven parasitized nests. Two of the remaining four nests were too high to reach; both these nests were depredated during incubation. One nest was found with a cowbird nestling and no other nest contents; the nestling was removed. At the seventh nest, the parasitism event caused nest failure. All three parasitized nests where we attempted to addle cowbird eggs were incubated long enough for any viable cowbird eggs to hatch, though none did (Table 4.5). The 2011 hatch rate of 0% is markedly lower than annual hatch rates of un-addled eggs in 2003–2009 (min = 60; max = 89; median = 75).

In 2011, only one of three parasitized nests that were incubated full-term hatched flycatcher nestlings (Table 4.6); the other two nests were incubated in excess of 20 days without any flycatcher eggs hatching. The fate of the parasitized nest that hatched a flycatcher nestling was unknown; we detected a 14-day-old flycatcher nestling on the nest rim but were unable to confirm that the nestling fledged. Success rates of parasitized nests that hatched at least one flycatcher nestling in 2003–2009 ranged from 44 to 100%. In parasitized nests that hatched flycatchers, the number of nestlings that survived to at least eight days old in 2011 (1.0/nest) was comparable to the numbers seen in 2003–2009 (min = 0.6; max = 1.5; median = 1.3).

Table 4.5. Brown-headed Cowbird Annual Hatch Rate in Willow Flycatcher Nests at Reclamation Study Areas from 2003 to 2011

Year	# Nests[1]	# CE	# CN	Hatch Rate
2003	4	4	3	75
2004	9	9	8	89
2005	9	9	7	78
2006	2	3	2	67
2007	6	8	6	75
2008	5	5	3	60
2009	8	8	5	63
2010[2]	4	4	1	25
2011[2]	3	3	0	0

[1] Total number of nests in which the cowbird egg hatched or was incubated full term (>10 days) are included.

[2] All cowbird eggs were addled at least once.

Table 4.6. Willow Flycatcher Nesting Success for Parasitized Nests at Reclamation Study Areas from 2003 to 2011

Year	# Nests[1]	# Nests with Flycatcher Nestlings[2]	# Nests with Flycatcher Fledges[3]	# Flycatcher Nestlings of Banding Age[4]	# Flycatcher Fledges[5]

2011[6]	3	1 (33)[7]	--[8]	1 (1.0)	--

[1] Total number of parasitized nests in which flycatcher eggs hatched or were incubated long enough to hatch (>14 days).

[2] Total number of parasitized nests that hatched flycatcher nestlings. Percentage of total nests is indicated in parentheses.

[3] Total number of parasitized nests that produced flycatcher fledges. Percentage of nests with nestlings is indicated in parentheses.

[4] Total number of nestlings that reached at least banding age (8 days). Number of nestlings per nest with nestlings is indicated in parentheses.

[5] Total number of nestlings that fledged. Number of nestlings per parasitized nest with nestlings is indicated in parentheses.

[6] All cowbird eggs were addled in these nests.

[7] The eggs in the other two nests failed to hatch; both were incubated at least 20 days.

[8] The flycatcher nestling was last seen in the nest on day 14. It is unclear whether it successfully fledged.

Mayfield Nest Success and Nest Productivity

Mayfield survival probability (MSP) ranged from 0.198 at Mesquite to 1.000 at Pahranagat and was 0.467 for all sites combined (Table 4.7). At all sites, 40 nestlings were confirmed to have fledged from 41 nests of known outcome (mean number of fledglings/nest = 0.98, SE = 0.19). Fecundity across study areas ranged from 0.00 to 2.83 young per female and averaged 1.18 (SE = 0.25) (Table 4.8).

Table 4.7. Daily Survival Rates and Mayfield Survival Probabilities (MSP) for Willow Flycatcher Nest Stages at Reclamation Study Areas, 2011*

Study Area	Nest Stage[1]	Nest Losses/ Observation Days	Daily Survival Rate	Mayfield Survival Probability

Total	**40**	**41**	**0.98 (0.19)**	**34**	**1.18 (0.25)**

* Productivity calculations include nests that contained flycatcher eggs and had a known outcome. Fecundity calculations include all females for which nest outcome was known.

NDOW Study Areas

Nest Monitoring

We documented 38 willow flycatcher nesting attempts at Key Pittman, River Ranch, and Warm Springs; 36 of these nests were known to contain flycatcher eggs and were used in calculating nest success and productivity. Fourteen (39%) nests were successful and fledged young, and 20 (56%) failed. Fate was unknown at two (5%) nests. Nest success was 42% at Key Pittman, 0% at River Ranch, and 100% at Warm Springs (Table 4.9).

Twenty-one nesting females, all of which were known to have produced at least one egg, were followed through all of their nesting attempts. One additional female was documented for which no nesting attempt was found. Of the 21 nesting females, 9 had one nesting attempt, 7 had two nesting attempts, and 5 had three nesting attempts. All 12 females with multiple nesting attempts renested after failed nests.

Table 4.9. Summary of Willow Flycatcher Nest Monitoring Results at NDOW Study Areas, 2011

[2] WE = willow flycatcher egg.

[3] Only nests with at least one flycatcher egg were used in percentage calculations. Percentages are given in parentheses.

[4] Parasitized nests include all nests that contained at least one flycatcher egg and one cowbird egg, regardless of nest fate. Percentages include only nests with at least one flycatcher egg and for which contents could be determined.

Nest Failure

Depredation was the major cause of nest failure, accounting for 59% (13 of 22) of all failed nests (Table 4.10) and 65% (13 of 20) of nests that failed after flycatcher eggs were laid. Two nesting attempts (9% of all failed nests) were abandoned prior to willow flycatcher eggs being laid, and four nests (18%) were deserted. One nest (5%) failed because of Brown-headed Cowbird parasitism (see below for more details on parasitism), and all nestlings died in two nests (9%) that were still being tended by adult flycatchers.

Table 4.10. Summary of Causes of Willow Flycatcher Nest Failure at NDOW Study Areas, 2011*

Study Area[1]	Total # Nests	All Failed Nests	Abandoned	Deserted	Depredated	Parasitized	Addled	Nestling(s) died in nest
KEPI	33	18	2 (11)	3 (17)[2]	11 (61)	0	0	2 (11)
RIRA	4	4	0	1 (25)	2 (50)	1 (25)	0	0
WMSP	1	0	0	0	0	0	0	0
Total	**38**	**22**	**2 (9)**	**4 (18)**	**13 (59)**	**1 (5)**	**0**	**2 (9)**

* All nesting attempts (those with and without flycatcher eggs) are included. Percentage of failed nests is shown in parentheses for each cause of failure.

[1] KEPI = Key Pittman WMA, RIRA = River Ranch, WMSP = Warm Springs Natural Area.

[2] All nests deserted during incubation; structure of one nest damaged, possibly from a depredation attempt.

Brood Parasitism

Four of 34[2] nests (12%) with flycatcher eggs and known contents were brood parasitized by Brown-headed Cowbirds (Table 4.11). All four nests failed. In one case, the parasitism event coincided with the disappearance of any flycatcher eggs. In another, the parasitism event coincided with the disappearance of two of three flycatcher eggs, and the remaining flycatcher egg disappeared a few days later. The female

[2] Table 4.9 shows 36 nests known to contain at least one flycatcher egg. When calculating brood parasitism rates, however, two nests whose contents could not be determined were excluded from calculations (e.g., nesting attempts that were discovered late in the nesting cycle).

flycatcher continued to incubate the cowbird egg, which had been addled. One nest was deserted with two flycatcher eggs and a cowbird egg. In the remaining nest, the cowbird nestling was removed but the flycatcher nestling developed very slowly and eventually died in the nest. Brood parasitism was 11% at Key Pittman, 75% at River Ranch, and 0% at Warm Springs (see Table 4.9).

Table 4.11. Fates of Willow Flycatcher Nests Parasitized by Brown-headed Cowbirds in Key Pittman, River Ranch, and Warm Springs Study Areas, 2011*

Study Area[1]	Nest ID Code	Outcome[2]
KEPI	46B	CN removed shortly after hatching. WN developed very slowly and eventually died in the nest.
RIRA	110A	WE disappeared when CE appeared.
	110B	Nest deserted with two WE and one CE.
	110C	Two of three WE disappeared when CE appeared. Last WE disappeared a few days later.

* All nesting attempts are included.

[1] KEPI = Key Pittman WMA, RIRA = River Ranch.

[2] WE = willow flycatcher egg, CE = cowbird egg, WN = willow flycatcher nestling, CN = cowbird nestling.

Cowbird Egg Addling

Three nests at River Ranch were parasitized; one nest was too high to reach but was deserted during incubation, and the parasitism event caused failure at another nest. We addled the cowbird egg at the third nest at River Ranch. Partial depredation of this nest resulted in the loss of the remaining flycatcher egg; the female flycatcher continued to incubate the cowbird egg, which never hatched. We removed one cowbird nestling from a nest at Key Pittman that was found late in incubation. This nest also failed, with a lone flycatcher nestling developing very slowly and eventually dying in the nest.

Mayfield Nest Success and Productivity

Mayfield survival probability (MSP) was 0.447 at Key Pittman. MSP could not be calculated across all nest stages at River Ranch and Warm Springs because of lack of data for some stages. MSP was 0.375 for all three sites combined (Table 4.12). At all sites, 33 nestlings were confirmed to have fledged from 34 nests of known outcome (mean number of fledglings/nest = 0.97, SE = 0.22). Fecundity across study areas ranged from 0 to 3.0 young per female and averaged 1.65 (SE = 0.28) (Table 4.13).

Table 4.12. Daily Survival Rates and Mayfield Survival Probabilities (MSP) for Willow Flycatcher Nest Stages NDOW Study Areas, 2011*

Study Area	Nest Stage[1]	Nest Losses/ Observation Days	Daily Survival Rate	Mayfield Survival Probability
Key Pittman	1	1/42	0.976	0.950
	2	12/277	0.957	0.566
	3	3/224	0.987	0.831
	MSP all stages = 0.447			
River Ranch	1	2/5	0.600	0.335
	2	2/13.5	0.852	0.127
	3	0/0		
	MSP all stages = N/A[2]			

Table 4.12. Daily Survival Rates and Mayfield Survival Probabilities (MSP) for Willow Flycatcher Nest Stages NDOW Study Areas, 2011* (Continued)

Study Area	Nest Stage[1]	Nest Losses/ Observation Days	Daily Survival Rate	Mayfield Survival Probability
Warm Springs	1	0/0		
	2	0/13	1.000	1.000
	3	1/14	1.000	1.000
	MSP all stages = N/A[2]			
Total	**1**	**3/47**	**0.936**	**0.868**
	2	**14/303.5**	**0.954**	**0.545**
	3	**4/238**	**0.983**	**0.792**
	MSP all stages = 0.375			

* Mayfield survival probability was calculated using 2.14-day egg laying, 12.85-day incubation, and 13.76-day nestling stages.

[1] 1 = egg laying, 2 = incubation, 3 = nestling.

[2] MSP cannot be calculated for all stages because of lack of data.

Table 4.13. Willow Flycatcher Nest Productivity (Young Fledged per Nest) and Fecundity (Young Fledged per Female) at NDOW Study Areas, 2011*

Study Area	Young Fledged	# Nests	Productivity Mean (SE)	# Females	Fecundity Mean (SE)
Key Pittman	30	29	1.03 (0.24)	16	1.88 (0.29)
River Ranch	0	4	0.00 (0.00)	3	0.00 (0.00)
Warm Springs	3	1	3.00	1	3.00
Total	**33**	**34**	**0.97 (0.22)**	**20**	**1.65 (0.28)**

* Productivity calculations include nests that contained flycatcher eggs and had a known outcome. Fecundity calculations include all females.

DISCUSSION

Reclamation Study Areas

Number of Breeding Flycatchers

In 2011, willow flycatcher nesting was documented at six Reclamation study areas (Pahranagat, Mesquite, Mormon Mesa, Muddy River, Topock Marsh, and Bill Williams). No flycatchers were documented at Littlefield, which held breeding flycatchers in 2009 and 2010 but was scoured by floods in December 2010. Given that southwestern riparian ecosystems experience dynamic change and are not ecologically static (Periman and Kelly 2000), willow flycatcher occupancy and nesting are likely to be affected by changes in habitat suitability, with breeding flycatchers detected at a given site in one year and not in another. The number of flycatcher pairs recorded at Mormon Mesa, Muddy River, and Bill Williams was comparable to that recorded over the last several years. Mesquite had seven pairs in both 2011 and 2010, which was a drop from the number of pairs recorded in the previous four years (range 11–15). The main breeding site at Mesquite was dry in 2009 and nesting success was poor that year (McLeod and Koronkiewicz 2010). Flycatchers appeared to respond to the poor conditions by returning to other breeding sites in 2010 rather than returning to Mesquite (McLeod and Pellegrini 2011), and the number of breeding flycatchers at Mesquite was consequently reduced. It is unclear why the number of breeding pairs at Mesquite remained low in 2011 despite wet conditions at Mesquite West (see Chapter 2) at the beginning of the breeding season. It is possible that habitat suitability in the western portion of

Mesquite West, which is a mix of tamarisk and coyote willow and was unoccupied in 2011, has been reduced by tamarisk beetle defoliation.

Pahranagat had six breeding pairs in 2011, the lowest number recorded since 2003 (range 8–15 pairs). Monitoring in future years will help determine whether this is a temporary decline at Pahranagat or whether the amount of suitable habitat could be decreasing because of the reduced amount of surface water at the site in 2008–2011(see Chapter 2). There is evidence that the spatial distribution of nests within the main breeding site at Pahranagat has shifted over the years, moving away from the interior of the site, which was formerly inundated, and toward the periphery of the site, which is still in close proximity to surface water (NAU, unpubl. data).

Topock Marsh had five resident flycatchers, consisting of three unpaired males and one pair, the lowest number of resident individuals recorded since monitoring began in 1998. The number of resident flycatchers at Topock has been declining steadily since 2004. Water levels were exceptionally low in 2011 (see Chapter 2), which may have contributed to the continuing decline.

Nest Success

Nest success alone is an incomplete measure of the production of young. Successful nests produce from one to four young, and variations in nest productivity are not reflected in nest success rates. In addition, although every failed nest attempt lowers percent nest success and MSP, success of a subsequent nesting attempt may result in the same number of young produced as if the initial nesting attempt had been successful. Thus, nest productivity (young produced per nesting attempt) and fecundity (young produced per female) in conjunction with nest success provide additional information on the success of a given breeding season. Nest success at Pahranagat (100%) was, as it has been every year since 2003, higher than the average for all study areas. Productivity (2.43 young per nest) and fecundity (2.83 young per female) at Pahranagat in 2011 were also the highest recorded at any Reclamation study area, demonstrating that Pahranagat continues to be a highly productive site for willow flycatchers.

Percent nest success was essentially unchanged at Mesquite compared to 2010, but fecundity in 2011 (0.43) was less than half that of 2010 (1.00), and only three fledglings were produced. Fecundity was also low in 2009 (0.25). The main breeding site at Mesquite was dry during much of the breeding season in 2009 and after mid-June 2011, and dry conditions may be related to poor flycatcher reproduction (Moore and Ahlers 2008). Percent nest success, productivity, and fecundity at Mormon Mesa were all similar to what they had been in 2010. Muddy River, Topock, and Bill Williams continued to exhibit annual fluctuations in reproductive metrics, but sample sizes are too low to attribute much significance to the rates observed in 2011. Nest success results again illustrate that the demographic patterns of passerine populations often vary year to year, and sometimes to a very large degree (Wiens 1989a). The variable patterns of nest success observed at the study areas over many years demonstrate the need for long-term data.

Nest Failure

As in 2003–2010, depredation was the major cause of willow flycatcher nest failure, accounting for 52% of all failed nests in 2011. These results are consistent with those reported at the Reclamation study areas from 1998 to 2002 (Braden and McKernan unpubl. data) and at sites across Arizona from 1996 to 2008 (Graber et al. 2007, Ellis et al. 2008, Graber and Koronkiewicz 2009a), which indicate depredation as accounting for the majority of all willow flycatcher nest failures. Factors influencing the increases and decreases in nest depredation at the monitored study areas are inherently complex and at this time remain undetermined. For open-cup nesting passerines, nest depredation rates can vary year to year, and sometimes substantially, with depredation of eggs and young ultimately linked to landscape

characteristics and fluctuations in predator densities, abundance, and richness (Wiens 1989b, Robinson 1992, Howlett and Stutchbury 1996).

In 2008, Northern Arizona University (NAU) initiated a nest camera study in cooperation with SWCA on open-cup nesting passerines at selected study areas along the lower Colorado River and tributaries. The study used video and still cameras on real and artificial nests to identify depredation rates and nest predators. The study continued in 2009 and 2010, with video cameras deployed at flycatcher nests and still cameras at artificial nests. Marks on clay eggs indicated that most depredation events at Mesquite were from birds, while at Pahranagat both birds and rodents depredated artificial nests (NAU unpubl. data). Both Brown-headed Cowbirds and Yellow-breasted Chats were identified by still cameras as depredating artificial nests. Cowbirds were also documented on video depredating flycatcher nests at Mesquite in both 2009 and 2010. A variety of avian predators were documented depredating flycatcher nests at Pahranagat. The study was continued in 2011, with video cameras deployed at real flycatcher nests at Pahranagat, but all flycatcher nests were successful and no depredation events were documented. Results of this study suggest that avian species may be important predators on flycatcher nests at Reclamation study areas. Ellis et al. (2008) also identified Cooper's Hawks (*Accipiter cooperii*) and Yellow-breasted Chats depredating flycatcher nests at sites in Arizona.

Brood Parasitism

Brood parasitism by Brown-headed Cowbirds across all Reclamation study areas ranged from 0 to 60% and averaged 19% (see Table 4.1). These results are consistent with those reported at the study areas from 1998 to 2010 (Braden and McKernan unpubl. Data; McLeod et al. 2008a; McLeod and Koronkiewicz 2009, 2010; McLeod and Pellegrini 2011), but these parasitism rates are higher than those reported at other monitored sites across Arizona in 1996–2006, which were less than 10% at most sites in most years (Graber et al. 2007, Ellis et al. 2008).

We observed multiple occasions in which the disappearance of flycatcher eggs coincided with the parasitism event. In this case, cowbirds were suspected of ejecting the eggs. Female Brown-headed Cowbirds are known to physically attack willow flycatcher nestlings (Woodward and Stoleson 2002), remove single eggs, and occasionally destroy entire broods after laying is complete or after hatching (Lowther 1993 as cited in Woodward and Stoleson 2002). In addition, cowbirds were photographed removing eggs from artificial nests during the 2008–2010 camera study, and cowbirds were documented on video depredating flycatcher nests during both the incubation and nestling phases. Therefore, it is likely that other depredation events on eggs and nestlings are attributable to cowbirds.

Parasitism does not invariably cause nest failure, but the success rate (18%) for parasitized nests at all study areas in 2003–2011 was less than half that of unparasitized nests (49%). Similar results were recorded for willow flycatchers in Oregon, with parasitism resulting in a 50% decrease in success rates compared to unparasitized nests (Sedgwick and Iko 1999) and at other sites in Arizona, where in 1996–2005, 20% of parasitized nests fledged flycatcher young vs. 57% of unparasitized nests (Ellis et al. 2008). Parasitized nests that did succeed in fledging flycatcher young at all study areas in 2003–2011 produced on average fewer young (1.3 young/nest) than did unparasitized nests (2.2 young/nest; $F_{1,249} = 21.24$, $P < 0.001$). Cowbirds may eject flycatcher eggs during the parasitism event, thus reducing clutch size, and cowbird young also cause interspecific nestling competition, as evidenced by the presence of severely underdeveloped nestlings in some parasitized nests. For all nests monitored from 2003 to 2011, 44% of nests that fledged a cowbird also fledged flycatcher young. This is a higher rate of success than that observed in Southwestern Willow Flycatchers at Kern River, California (9%; Whitfield and Sogge 1999), but comparable to that observed at other Arizona sites (40%; Ellis et al. 2008).

Female flycatchers may desert their nests after parasitism events and thus expend energy renesting and laying additional eggs. Given that adult flycatchers exhibit high site fidelity to breeding areas (Braden and McKernan unpubl. data, McLeod et al. 2008a, McLeod and Koronkiewicz 2009, this document) and renest most often after failed nests (Sedgwick 2000), females returning to sites with high brood parasitism may have reduced lifetime fecundity because they are expending energy on multiple failed nesting attempts over many years. An analysis of lifetime fecundity of females will be included in the summary report in 2012. In addition, willow flycatchers that fledge late in the season have been shown to have a lower survival rate than those that fledge early in the season (Paxton et al. 2007, McLeod et al. 2008a), suggesting additional hidden effects of parasitism and subsequent renesting on flycatcher demography.

Cowbird trapping and removal studies were initiated at Pahranagat, Mesquite, and Topock Marsh in 2003 and continued through 2007. Results of these studies showed that cowbird trapping appeared to lower parasitism rates in comparison to the pre-trapping period of 1998–2002 only at Pahranagat, with no parasitism detected during trapping years (McLeod et al. 2008a). No cowbird trapping was completed in 2008–2011, but even in the absence of cowbird trapping, no parasitism events were detected at Pahranagat in 2008, 2009, or 2011. One parasitism event was noted in 2010, and the nest was abandoned before flycatcher eggs were laid. This nest was located on the very edge of the site, adjacent to open, upland habitat, possibly increasing parasitism probability. These observations suggest that cowbird trapping may have lingering effects beyond the years in which trapping is completed.

We speculated that trapping might have affected the parasitism rate at Pahranagat but not the other study areas because Pahranagat consists of relatively small, isolated patches of riparian habitat rather than existing in a large, contiguous riparian corridor. The breeding site at Muddy River is a relatively small stand of tall trees and is bordered to the north by an extensive valley dominated by residential areas and agriculture and containing little riparian vegetation. Muddy River had 33–75% parasitism in six of the seven years when flycatchers have been monitored at the study area, and overall nest success was 26%, well below the average of 46% across all other study areas in those years. Although the breeding site at Muddy River is not as isolated from surrounding riparian vegetation as the site at Pahranagat, cowbird trapping at Muddy River has the possibility of reducing the parasitism rate and increasing flycatcher nest success, and we recommend that cowbird trapping be instituted at Muddy River.

Cowbird Egg Addling

We addled cowbird eggs and removed cowbird nestlings in all study areas except Pahranagat in 2011. Pahranagat was not included because it is still part of the 5-year post-cowbird-trapping experiment. Though sample size is small, addling cowbird eggs seemed to reduce the hatch rate of cowbird eggs. Furthermore, none of the females deserted their nests after we addled cowbird eggs. One female in a non-Reclamation study area from whose nest a cowbird nestling was removed also continued to raise the remaining flycatcher nestling. While flycatcher hatch rates and productivity were not improved by the program in 2011, this is not necessarily due to the program itself so much as low parasitism rates and high rates of nest failure due to addling where parasitism did occur. We recommend this program be continued in the future. Field personnel should also continue to practice egg addling at the beginning of the season with button quail eggs to maximize the effectiveness of shaking eggs in preventing hatching.

NDOW Study Areas

At Warm Springs, a fire during the breeding season of 2010 affected all sites and reduced the availability of suitable habitat (see Chapter 2), and the number of breeding pairs declined correspondingly from three to one in 2010 and 2011, respectively. Many measures of nesting (number of breeding pairs, Mayfield nest success, and rate of brood parasitism) were similar at Key Pittman between 2010 and 2011.

Productivity and fecundity were lower in 2011 (1.03 and 1.88, respectively) than in 2010 (1.23 and 2.03, respectively), but there was no statistically significant difference in either fecundity or productivity between years.

Cowbird parasitism was high (75%) at River Ranch, and none of the four nests at this site was successful. Low nest success is further indication of poor habitat quality at River Ranch (see Chapter 3 for a discussion of within-year movement and the presence of second-year individuals at River Ranch).

Video cameras were deployed on flycatcher nests in both 2010 and 2011 at Key Pittman. Two depredation events were recorded on video in 2011 (NAU unpubl. data), one by a kingsnake (*Lampropeltis getulus*) and the other by a Sharp-shinned Hawk (*Accipiter striatus*). Field personnel also witnessed a depredation event by a short-tailed weasel (*Mustela frenata*).

Chapter 5

VEGETATION AND HABITAT CHARACTERISTICS

INTRODUCTION

Our objective for vegetation sampling is to provide a quantitative summary of the floristic and structural conditions within occupied territories in various vegetation types. These descriptive summaries will provide guidance for managers working to restore and create riparian habitat to meet the obligations of the LCR MSCP and will provide a means to evaluate habitats to determine if they resemble occupied flycatcher territories. The Pahranagat study area was excluded from the characterization of occupied territories because the vegetation consists primarily of very large and widely spaces trees, and these characteristics are unique to the site and not likely to be replicated in restoration areas. In 2011, we completed vegetation sampling within occupied territories only at Bill Williams because of the relatively low sample size of vegetation plots obtained at this study area over previous years. Sampling at all other study areas was discontinued because of adequate sample sizes from previous years. A combined analysis of all years of vegetation data will be presented in a summary report in 2012.

METHODS

We described and measured vegetation and habitat features following a modification of the methods of James and Shugart (1970). Vegetation characteristics were measured within a 5-m-radius circle. To avoid disrupting flycatcher breeding activities, we measured vegetation late in the summer when the nest, territory, and adjacent flycatcher territories were inactive.

In 2008, we measured vegetation and habitat characteristics at one plot for each resident (i.e., detected for at least one week) male flycatcher we identified, regardless of whether or not he obtained a mate. Plot center locations were determined as soon as territories were identified. We estimated the center of the male's activity by observing his use of singing perches and selecting a location that was approximately equidistant from the perches at the perimeter of his use area. We then proceeded in a randomly selected compass direction for a randomly selected distance between 0 and 20 m. We used additional random numbers to select the exact location in which to hang a temperature/humidity data logger (see Chapter 6) and used that location as plot center. This process resulted in the random selection of a point that was still within the male's territory. The sampling points were marked in the field with flagging that remained in place over the winter.

In 2009, we identified the territory center for each resident male as described above. If an existing sampling point from 2008 was within 20 m of the territory center identified in 2009, we assigned that existing point to the current territory. If there was no existing point within 20 m of the territory center, we located a new sampling point as described above. All sampling points that were assigned to active territories in 2009 were marked with flagging that remained in the field over the winter. We repeated this point selection procedure for territories that were active in 2010 and 2011, assigning a sampling point that was used in the previous year if one was within 20 m of the current territory and selecting a new sampling point if no existing point were available. Sampling points that were identified in 2010 but were not within 20 m of a territory center in 2011 were resampled in 2011.

At each plot, we laid out four 5-m-long ropes from plot center, one in each of the four cardinal directions. Each rope was marked at 1 m and 5 m from the center of the plot. At plot center and at 1 m and 5 m from

the center of the plot in each cardinal direction, we measured vertical foliage density using a 7.5-m-tall survey rod. Working our way up the rod, we recorded the presence of vegetation, by species, within a 10-cm radius of the rod in 0.1-m intervals (presence of the species within the 0.1-m interval equaled one "hit" on the rod), and summed all hits in 1-m intervals. Presence of dead vegetation (snags) was recorded in the same manner, but not identified to species. If canopy vegetation continued above 8.0 m, we estimated the number of hits as zero, greater than five, or less than five hits per 1-m interval until the canopy vegetation stopped (modified from Rotenberry 1985).

We measured total canopy closure using a Model-A spherical densiometer at 1 m north and south of the center of each plot and averaged these measurements to obtain a single canopy closure value for each plot. We measured average canopy height within each plot by selecting a representative tree and using a survey rod or a clinometer and measuring tape to measure the height of the selected tree. We estimated percent woody ground cover, alive and dead, within 0.5 m of the ground using a Daubenmire-type frame with the lower edge of the frame centered at 1 m north, south, east, and west of plot center. These percentages were averaged to obtain a single measure of percent woody ground cover for each plot.

We tallied the number of live stems for each species within 5 m of the center of the plot. Stems were tallied if they were at least 1.4-m tall and >2.5 cm in diameter at 10 cm above the ground. Stems were tallied by the following diameter at breast height (dbh) categories: <1 cm, 1–2.5 cm, 2.6–5.5 cm, 5.6–8 cm, 8.1–10.5 cm, and 10.6–15 cm. Any stems >15 cm dbh were measured and the exact dbh was recorded. Dead stems were also tallied in these categories, but not identified to species. We marked each stem with a piece of chalk after it was tallied to facilitate accurate stem counts.

During vegetation sampling in 2003–2007, if a stem branched above 10 cm but below 1.4 m above the ground, only the largest stem was tallied. In habitats (e.g., tamarisk) where stems frequently branch in this height interval, this method of counting stems may underestimate the density of stems that form an important part of the habitat structure. Therefore, in 2008–2011 we tallied stems as we had in previous years and then for each stem that branched between 10 cm and 1.4 m from the ground, we tallied the number of additional stems that were at least 2.5 cm in diameter at 10 cm above the point where it branched from the main stem.

Additional information recorded at each plot included the date when the measurements were taken, observer initials, and UTM coordinates for each plot center.

Data Analyses

We used high-resolution aerial photography and field knowledge of each study area to delineate clusters of territories that occur within habitat patches of similar floristics and canopy height. Vegetation characteristics were then summarized for each habitat type. For each habitat type, we give the corresponding vegetation classification as defined in Younker and Andersen (1986) and used in the LCR MSCP. We also pooled data across habitat types that fell under a single vegetation classification and present summary statistics for each vegetation classification. We used SPSS® Version 16.0 (SPSS Inc.) software for statistical analyses.

Stem counts were grouped into the following size categories for analysis: ≤2.5 cm dbh, 2.6–8 cm dbh, and >8 cm dbh. For each size category, stem counts are reported separately for live and dead stems; the sum of these is the equivalent of the stem counts per size category that were reported in the 2003–2007 summary report (McLeod et al. 2008a). Vertical foliage density measurements above 8.0 m that were recorded as < or >5 hits per meter were converted to 2.5 and 7.5 hits, respectively, to allow analyses of these data as continuous rather than categorical. Vertical foliage density was calculated for each meter interval as the mean of the number of hits recorded within the interval at the nine locations in the plot.

In 2003–2007, we had measured vertical foliage density only at plot center and 1 m from plot center in each cardinal direction, and foliage density measures per meter interval were presented as the sum of the hits recorded at the five locations in the plot. Thus, vertical foliage data presented in reports from 2003 to 2007 should be divided by 5 to be comparable to data presented here. In the five-year summary report (McLeod et al. 2008a), vertical foliage data were grouped into three categories of above, at, and below the nest. We used average nest height as measured in 2003–2011 in each vegetation type to demarcate vertical foliage categories in 2011. As with stem counts, vertical foliage data are reported separately for live and dead vegetation.

Percent native vegetation was calculated as the average of the percent basal area that was native and the percent native vertical foliage hits. To obtain basal area, we multiplied the number of stems tallied in each size class by the average basal area of a stem in that class, given an even distribution of stems within each size class. For data collected in 2003–2007 (reported in McLeod et al. 2008a), we did not use vertical foliage data to calculate percent native because all vertical foliage data were collected within 1 m of plot center and represented only a small portion of the plot. We included vertical foliage data in the percent native calculations in 2008–2011 to account for the influence of stems that were too small to be tallied or were rooted outside the 5-m-radius circle but overhung the plot.

RESULTS

We measured vegetation at Bill Williams at four occupied territories and four territories that were occupied in 2010 but not in 2011. The eight territories are located in five survey sites at Bill Williams: Site #3, Site #4, Burn Edge, Planet Ranch Road, and Cougar Point. Of the four occupied territories, three had nesting flycatchers and one was occupied by an unpaired male. Small sample sizes preclude any comparison between territories occupied by nesting pairs versus those occupied by unpaired males; data collected in 2011 will be combined with data collected in previous years for this comparison, which will be presented in a five-year summary report in 2012. Data from territories that were occupied in 2010 but not in 2011 are not included in the 2011 data presented below but may be used in future analyses to identify any changes in vegetation that may lead to territory abandonment. This analysis would also be presented in the summary report.

We delineated the following habitat types: 1) Goodding willow with tamarisk understory, and 2) cottonwood/willow. Goodding willow with tamarisk understory occurred in Site #3, Site #4, and Burn Edge, while cottonwood/willow was present at Planet Ranch Road and Cougar Point. Average nest height recorded in 2003–2011 and used to assign vertical foliage strata for each vegetation category were 4.2 m for Goodding willow with tamarisk understory and 2.5 m for cottonwood/willow.

Although the vegetation types delineated in this report differ from one another in vertical structure and floristic composition, all fall within the definition of cottonwood-willow habitat (cottonwoods and willows constituting at least 10% of total trees) as described in Younker and Anderson (1986) and used in the LCR MSCP. The cottonwood/willow habitat type as delineated in this report falls under the definition of cottonwood-willow Type III (no understory, with the canopy layer from 4.5–6.0 m), while Goodding willow with tamarisk understory as delineated in this report falls under the definition of cottonwood-willow Type I (three definitive layers of vegetation with the majority of the vegetation volume at 6.0 m or more).

Vegetation characteristics of each habitat type are summarized in Table 5.1. Habitat characteristics varied between and within habitat types.

Table 5.1. Summary of Vegetation Characteristics at Occupied Southwestern Willow Flycatcher Territories in Varying Habitat Types, Lower Colorado River and Tributaries, 2011*

Parameter	SAGO with TASP understory (C-W Type I) (n=2)	POFR and SAGO (C-W Type III) (n=2)
Average canopy height (m)	6.3 (0.5)	7.4 (0.7)
	5.8–6.8	6.7–8.0
% total canopy closure	90.9 (3.9)	97.4 (1.6)
	87.0–94.8	95.8–99.0
% woody ground cover	33.9 (21.4)	37.1 (31.6)
	12.5–55.3	5.5–68.8
# live stems ≤2.5 cm dbh per ha	1846 (1210)	1210 (1210)
	637–3056	0–2419
# live stems 2.6–8 cm dbh per ha	3183 (764)	9486 (446)
	2419–3947	9040–9931
# live stems >8 cm dbh per ha	573 (318)	1210 (64)
	255–891	1146–1273
# dead stems ≤2.5 cm dbh per ha	446 (191)	1337 (955)
	255–891	382–2292
# dead stems 2.6–8 cm dbh per ha	827 (191)	764 (255)
	637–1019	509–1019
# dead stems >8 cm dbh per ha	64 (64)	0 (0)
	0–127	0–0
Percent native	1.7 (1.2)	99.1 (0.6)
	0.4–2.9	98.8–100.0
Live vertical foliage (hits) below average nest height	6.3 (0.4)	1.9 (1.1)
	5.9–6.7	0.8–3.0
Live vertical foliage (hits) at average nest height	2.7 (0.0)	3.9 (1.9)
	2.7–2.7	2.0–5.8
Live vertical foliage (hits) above average nest height	2.2 (0.8)	13.7 (2.4)
	1.4–3.0	11.2–16.1
Dead vertical foliage (hits) below average nest height	12.7 (1.8)	3.4 (2.7)
	10.9–14.4	0.8–6.1
Dead vertical foliage (hits) at average nest height	0.6 (0.4)	1.8 (1.7)
	0.1–1.0	0.1–3.6
Dead vertical foliage (hits) above average nest height	0.2 (0.2)	1.0 (1.0)
	0–0.4	0–2

* Data are presented as mean, standard error, and range. Stem counts include only the largest stem of any cluster that branched above 10 cm above the ground. SAGO = Goodding willow, TASP = tamarisk, POFR = cottonwood, C-W = cottonwood-willow.

The proportion of stems omitted from stem counts by counting only the largest stem of a cluster that branched between 10 cm and 1.4 m above the ground varied both by size and species of the main stem (Table 5.2). Larger stems typically had more branches that were omitted.

Vertical foliage profiles for each habitat type are shown in Figures 5.1–5.2. Average nest height in each habitat type, as recorded in 2003–2011, is also shown on each graph. In both habitat types, the proportion of dead vegetation in the vertical profile was highest immediately above the ground and declined with increasing height. The densest live foliage occurred 3–5 m above the ground, at or above average nest height.

Table 5.2. Proportion of Stems Omitted from Stem Counts

Size category[1]	Species			
	Tamarisk	Coyote willow	Goodding willow	Dead stems
≤2.5 cm dbh	0.12	--	0.0	0.05
2.6–8 cm dbh	0.67	--	0.0	0.52
>8 cm dbh	1.46	--	0.0	2.0

[1] Size category indicates the size of the main stem that was tallied. All stems that were omitted from the stem count are equal to or smaller than the size of the main stem.

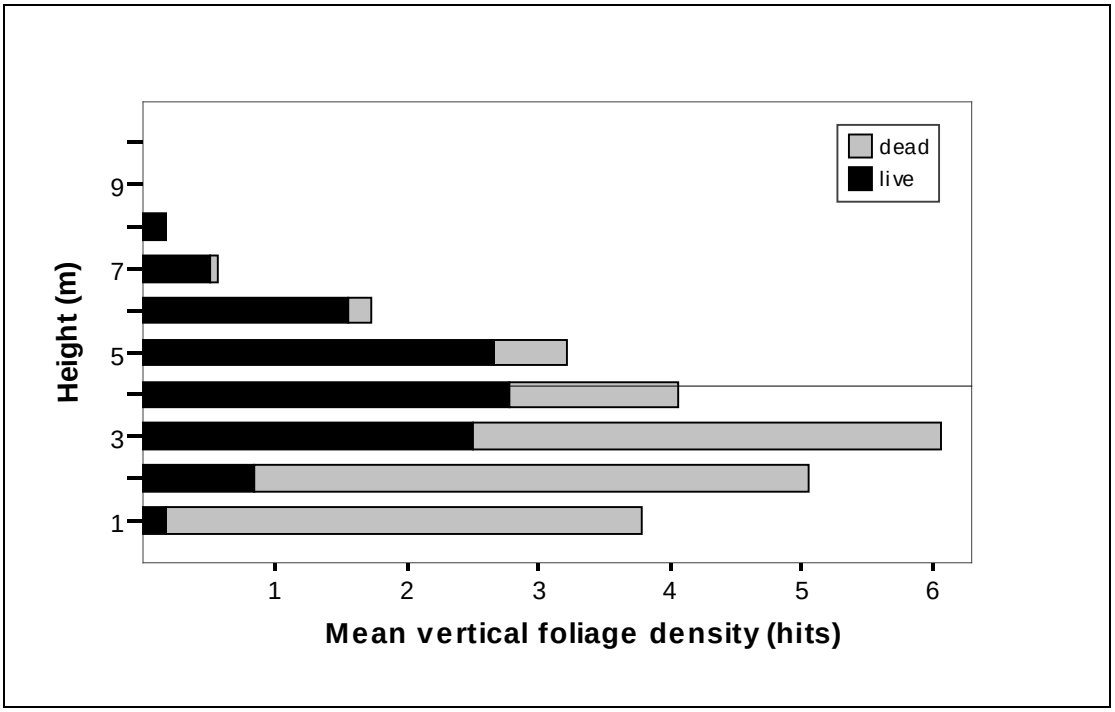

Figure 5.1. Vertical foliage density at occupied willow flycatcher territories in Goodding willow with tamarisk understory habitat type, 2011. Horizontal line shows average nest height in this habitat type in 2003–2011. This habitat type is also cottonwood-willow Type I.

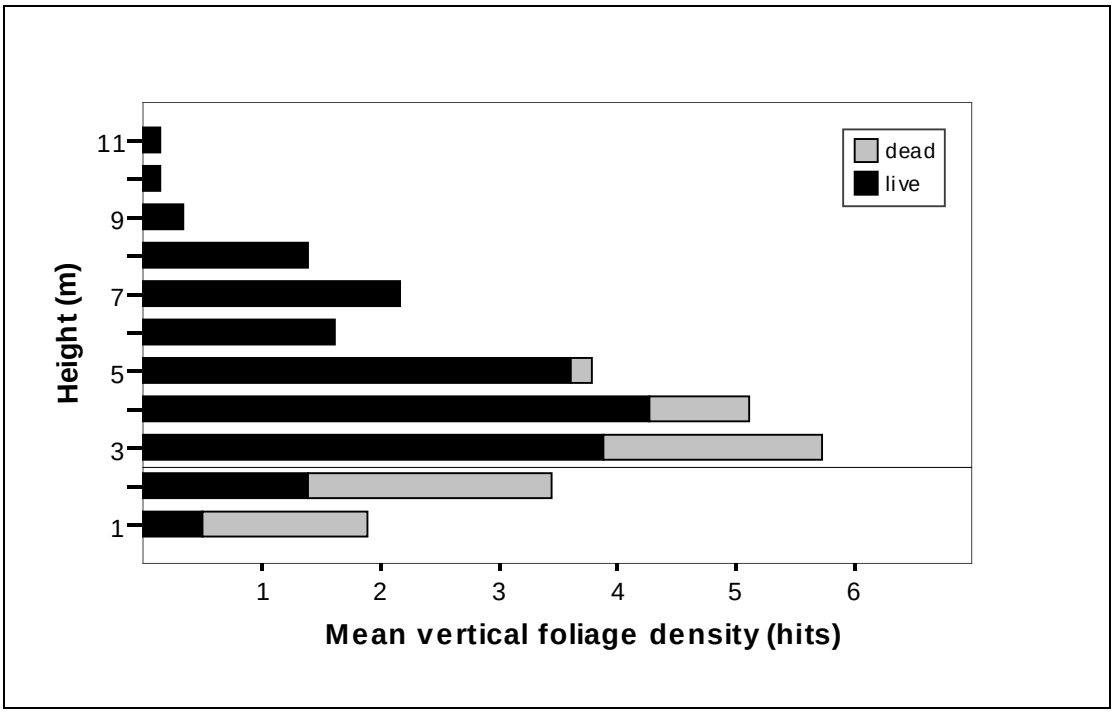

Figure 5.2. Vertical foliage density at occupied willow flycatcher territories in cottonwood/willow habitat type, 2011. Horizontal line shows average nest height in this habitat type in 2010–2011. This habitat type is also cottonwood-willow Type III.

DISCUSSION

The purpose of vegetation measurements of occupied habitat is to provide quantitative guidelines for restoration efforts. The limited data collected in 2011 preclude any meaningful summary of habitat characteristics and any comparison between vegetation types. In a summary report to be completed in 2012, data from 2011 will be combined with other data collected within active territories in prior years to provide a more comprehensive description of each habitat type.

Chapter 6

MICROCLIMATE

INTRODUCTION

Our objective for microclimate sampling is to provide a quantitative summary of microclimate conditions within occupied territories in various vegetation types. These descriptive summaries will provide guidance for managers working to restore and create riparian habitat to meet the obligations of the LCR MSCP and will provide a means to evaluate habitats to determine if the microclimate resembles that in occupied flycatcher territories. The Pahranagat study area was excluded from the characterization of occupied territories because the study area is approximately 650 m higher in elevation and experiences a cooler climate than the LCR MSCP planning area. In 2011, we collected microclimate data only at Bill Williams; adequate sample sizes had been achieved at all other study areas in previous years.

METHODS

Temperature and Humidity Measurements

Measurements of temperature and humidity were recorded automatically every 15 minutes using a HOBO H8 Pro (Onset Computer Corporation, Pocasset, MA) that combines a thermometer (degrees Celsius), humidity monitor, and digital data logger. We camouflaged all HOBO units by placing them in an inverted small, plastic container coated with spray adhesive and local vegetation. The opening at the bottom was covered with shadecloth, allowing free air circulation around the unit.

In 2010, we collected microclimate measurements at one location for each resident male flycatcher we identified, regardless of the length of time the male was resident and whether or not he obtained a mate. One HOBO unit was placed within each active flycatcher territory. We estimated the center of the male's territory (see Chapter 5) and then determined the location of the HOBO unit by means of the following instructions and the use of random number sequences:

1) The compass direction to walk from the territory center, given in degrees from north, was determined from a random number sequence.

2) The distance (between 0 and 20 m) to walk in the designated direction was determined from a random number sequence. Once that distance was traveled, the closest woody tree or shrub was selected for data logger placement.

3) The HOBO unit was placed at a randomly selected height within the range of flycatcher nest heights documented at that study area in 2003–2007 (McLeod et al. 2008a). The distribution of random numbers followed the distribution of nest heights. If the chosen tree or shrub was of insufficient height to accept the height from the random number sequence, then field personnel placed the HOBO unit at the first height in the sequence that was less than the height of the tree or shrub. If no nests had been previously recorded at that study area, field personnel used the height sequences from the nearest study area with known nests.

4) The distance (0–2 m) at which the HOBO was placed from the bole of the tree or center of the shrub was determined from a random number sequence. If the tree or shrub was of insufficient radius to accept the distance from the random number sequence, then field personnel placed the unit at the first number in the sequence that was less than the radius of the tree or shrub.

5) The compass direction, given in degrees from north, at which the unit was placed from the bole of the tree or center of the shrub was determined from a random number sequence. If there was no branch in this compass direction that would support the data logger at the height and distance specified in (3) and (4), field personnel proceeded clockwise around the tree or shrub until a suitable branch was located.

If, as presented in (3) and (4), a number from a subsequent random number sequence (sequence meaning a row in the random number table) was used because the number in the initial sequence was too high, then both sequences were considered used and no longer available for future use. If these directions took field personnel outside of the riparian zone or to a site without trees or shrubs, they returned to the territory center and used the next sequence of random numbers.

The HOBO logger locations representing active territories in 2010 at Bill Williams were marked in the field with flagging, which remained in place over the 2010–2011 winter. HOBO loggers were redeployed in these same locations in early May 2011. During the breeding season of 2011, we identified the territory center for each resident male. If an existing sampling point was within 20 m of the territory center identified in 2010, we assigned that existing point to the current territory. If there was no existing point within 20 m of the territory center, we located a new sampling point as described above. Sampling points that were identified in 2010 but were not within 20 m of a territory center in 2011 were resampled in 2011. Data from these points are not included in the 2011 data presented below but may be used in future analyses to identify any changes in vegetation that may lead to territory abandonment. All HOBO units were removed from the field at the end of the breeding season.

Soil Moisture Measurements

A ThetaProbe ML2x coupled to an HH2 Moisture Meter Readout (Macaulay Land Use Research Institute, Aberdeen, UK, and Delta-T Devices, Cambridge, UK, respectively) was used to gather soil moisture data. The soil moisture readings (nine per site) were recorded directly beneath the HOBO logger (plot center) and at 1.0 and 2.0 m from plot center in each cardinal direction. Soil moisture readings were collected when the HOBO logger was deployed and at two-week intervals throughout the breeding season until the HOBO logger was removed at the end of the season. Soil moisture was recorded both as voltage (mV) and as volumetric water content (%).[1] Soil type on the HH2 was set to mineral soil. For any soil moisture measurement point that was underwater, we recorded the depth of standing water and assigned a value of 994 mV, which is equivalent to 50% volumetric water content, or fully saturated soil. All mV values greater than 994 were also reassigned as 994 mV, because this reading represents fully saturated soil and because the mV to percent relationship becomes excessively nonlinear for mV readings above this point. Each time we collected soil moisture data, we also recorded the distance to the nearest standing water or saturated soil (as measured by visual estimate, GPS, or aerial photo) and recorded the approximate percentage, as estimated in the field by visual observation in combination with aerial photo, of the site within 20 and 50 m of the data logger that contained inundated or saturated soil.

A soil sample was collected from beneath each HOBO location that was new in 2011. Samples were approximately the size of a medium apple, collected from the surface down to and including a depth of 5 cm, and placed in a heavy zip-lock plastic bag labeled with the site designation. These samples will contribute to an ongoing analysis of soil texture, which strongly influences capillary action and therefore

[1] The soil moisture logger measures the dielectric constant of moist soil via a direct current voltage, which is converted to volumetric soil moisture with conversion tables. For very high (above ~1000 mV) or low (below ~90 mV) voltage readings, the HH2 reports volumetric soil moisture as "above" or "below" the table, respectively. To enable the use of all data, we analyzed and report only the mV readings. Both mV and percentage were recorded in the field to facilitate data proofing. Voltage is related to soil moisture as follows: $1.07 + 6.4V - 6.4V^2 + 4.7V^3 = 1.6 + 8.4\theta$, where θ = volumetric soil moisture.

overall soil moisture (Sumner 2000). Results of the soil texture analysis will be presented in the 2012 summary report.

Statistical Analyses

Soil moisture data were entered into a database as they were collected during the field season. We downloaded data from the HOBO data loggers into databases at the end of the field season. We merged all data to create one dataset for further analysis. We summarized the following variables for each HOBO location:

- Mean soil moisture from plot center to 2.0 m from plot center
- Distance to nearest standing water or saturated soil
- % of the area within 20 m of plot center that was inundated or saturated
- % of the area within 50 m of plot center that was inundated or saturated
- Maximum diurnal temperature
- Minimum nocturnal temperature
- Daily temperature range (diurnal maximum minus nocturnal minimum)
- Mean diurnal vapor pressure[2]
- Mean nocturnal vapor pressure

Soil moisture variables were summarized per visit, and temperature/humidity variables were summarized on a daily basis. We determined diurnal and nocturnal periods by using the actual daily sunrise and sunset times reported for the region by the National Weather Service (2011). We selected the above measures of temperature and humidity for analysis because they were the most highly correlated with other variables or were the most useful in distinguishing use areas from non-use locations (McLeod et al. 2008a). Territories were grouped according to habitat type (see Chapter 5), and microclimate variables were averaged for each habitat type over the following two-week periods to show how microclimate conditions changed throughout the breeding season: 16–31 May, 1–15 June, 15–30 June, 1–15 July, and 16–31 July. Data were also summarized by vegetation classification (see Chapter 5).

Analyses were conducted using SAS® Version 9.2 (SAS Institute 2009). Data are presented as mean (standard error) unless otherwise noted.

RESULTS

We collected microclimate data at two active territories that contained nesting pairs and four territories that were occupied in 2010 but not in 2011. Data from territories that were occupied in 2010 but not in 2011 are not included in the 2011 data presented below but may be used in future analyses to identify any changes in microclimate that may lead to territory abandonment. This analysis would be presented in a five-year summary report in 2012. One active territory was in Goodding willow with tamarisk understory, which falls under the cottonwood-willow Type I vegetation classification, and the other territory was in cottonwood/willow, which falls under cottonwood-willow Type III (see Chapter 5). Microclimate variables are summarized by two-week periods for each vegetation type in Tables 6.1 and 6.2. These same variables are plotted in Figures 6.1–6.9 to facilitate comparisons between vegetation types.

[2] Vapor pressure, unlike relative humidity, is not influenced by ambient temperature, and may be a more biologically meaningful measure of water content of the air (e.g., the relative vapor pressure inside and outside an egg determines whether the egg loses moisture). We calculated vapor pressure from the absolute humidity and temperature recorded by the HOBOs.

Table 6.1. Microclimate Measures in Southwestern Willow Flycatcher Territories in Goodding Willow with Tamarisk Understory, 2011*

Microclimate measure	May 16–31	June 1–15	June 16–30	July 1–15	July 16–31	August 1–15
Soil Moisture (n=1)[1]						
Mean soil moisture (mV)	894.7	831.7	750.7	758.0	752.8	731.3
Mean distance to nearest standing water	15.0	15.0	15.0	375.0	393.0	470.0
% of area within 20 m that was inundated	25.0	20.0	5.0	0.0	0.0	0.0
% of area within 50 m that was inundated	30.0	35.0	15.0	0.0	0.0	0.0
Temperature (n=1)[2]						
Mean maximum diurnal temperature (°C)	35.3 (0.8)	37.9 (0.6)	39.7 (0.3)	41.6 (0.7)	39.2 (0.5)	N/A
Mean minimum nocturnal temperature (°C)	11.8 (0.7)	12.3 (0.5)	16.5 (0.6)	19.7 (0.9)	20.6 (0.8)	N/A
Mean daily temperature range (°C)	23.4 (1.0)	25.6 (0.7)	23.2 (0.5)	21.9 (0.9)	18.7 (0.9)	N/A
Humidity (n=1)[2]						
Mean diurnal vapor pressure (Pa)	1309.5 (67.2)	1726.9 (118.4)	2249.5 (113.7)	2991.2 (126.2)	3063.0 (84.2)	N/A
Mean nocturnal vapor pressure (Pa)	1037.0 (48.0)	1308.9 (52.3)	1562.9 (72.3)	2297.7 (116.8)	2339.8 (94.6)	N/A

* Data are presented as mean (standard error). This habitat type is also cottonwood-willow Type I.
[1] Sample size indicates the number of data logger locations. No standard error is reported for periods in which soil moisture variables were measured only once.
[2] Sample size indicates the number of data logger locations. Mean and standard error are reported for daily readings within each time period.

Table 6.2. Microclimate Measures in Southwestern Willow Flycatcher Territories in Cottonwood/Willow, 2011*

Microclimate measure	May 16–31	June 1–15	June 16–30	July 1–15	July 16–31	August 1–15
Soil Moisture (n=1)[1]

% of area within 20 m that was inundated	55.0	60.0 (20.0)	40.0	85.0	50.0	60.0
% of area within 50 m that was inundated	70.0	50.0 (10.0)	65.0	45.0	60.0	50.0
Temperature (n=1)[2]						
Mean maximum diurnal temperature (°C)	29.9 (0.8)	32.6 (0.6)	35.2 (0.5)	35.0 (0.5)	35.3 (0.7)	N/A
Mean minimum nocturnal temperature (°C)	14.5 (1.0)	13.6 (0.7)	19.1 (0.8)	21.0 (1.0)	22.4 (0.8)	N/A
Mean daily temperature range (°C)	15.4 (1.3)	19.0 (0.9)	16.1 (0.6)	13.9 (1.1)	13.0 (0.9)	N/A
Humidity (n=1)[2]						
Mean diurnal vapor pressure (Pa)	1112.0 (43.0)	1269.8 (64.8)	1516.9 (50.4)	2312.6 (164.7)	2245.6 (114.6)	N/A
Mean nocturnal vapor pressure (Pa)	806.2 (25.2)	904.9 (42.3)	1114.3 (47.0)	1937.9 (147.3)	1873.1 (111.8)	N/A

* Data are presented as mean (standard error). This habitat type is also cottonwood-willow Type III.
[1] Sample size indicates the number of data logger locations. Mean and standard error are reported for time periods in which soil moisture variables were measured twice. No standard error is reported for periods in which soil moisture variables were measured only once.
[2] Sample size indicates the number of data logger locations. Mean and standard error are reported for daily readings within each time period.

AR064216

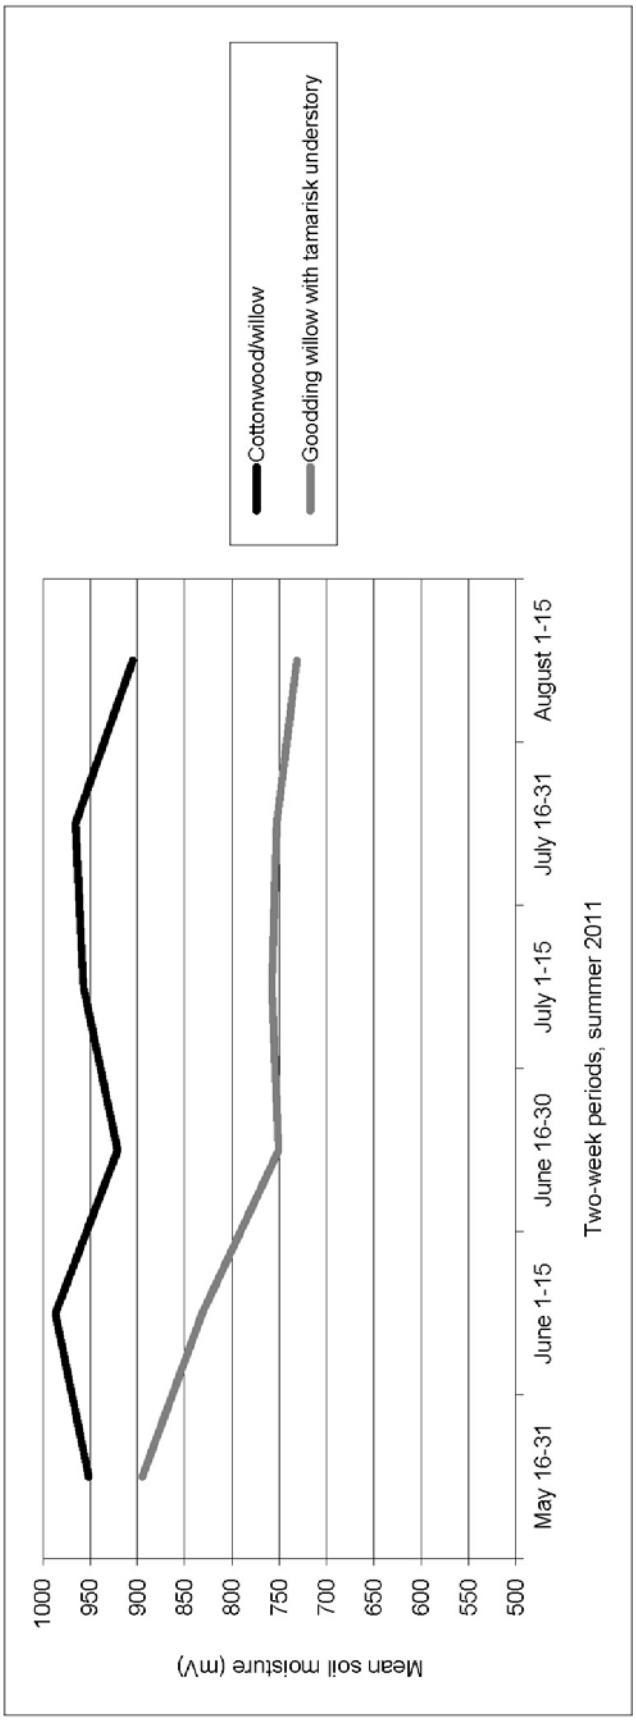

Figure 6.1. Mean soil moisture (mV) in Southwestern Willow Flycatcher territories in various vegetation types, lower Colorado River and tributaries, 2011. Cottonwood/willow = cottonwood-willow Type III, and Goodding willow with tamarisk understory = cottonwood-willow Type I. Data are summarized by two-week periods. Each vegetation type contained a single flycatcher territory.

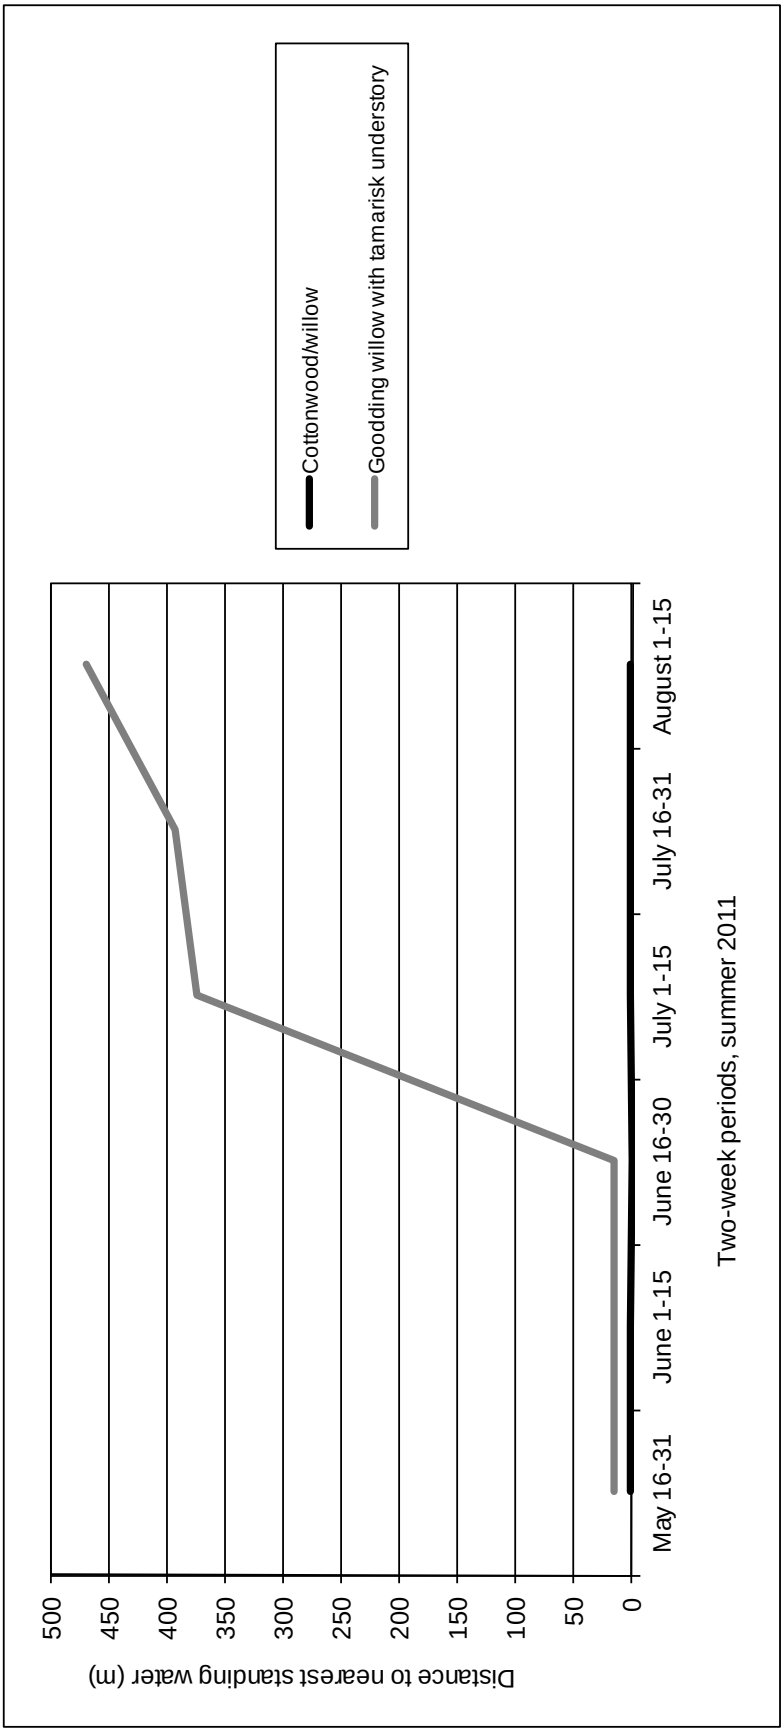

Figure 6.2. Distance (m) to standing water or saturated soil from Southwestern Willow Flycatcher territories in various vegetation types, lower Colorado River and tributaries, 2011. Cottonwood/willow = cottonwood-willow Type III, and Goodding willow with tamarisk understory = cottonwood-willow Type I. Data are summarized by two-week periods. Each vegetation type contained a single flycatcher territory. Data are presented as means for instances in which distance to water was measured more than once in a given two-week period.

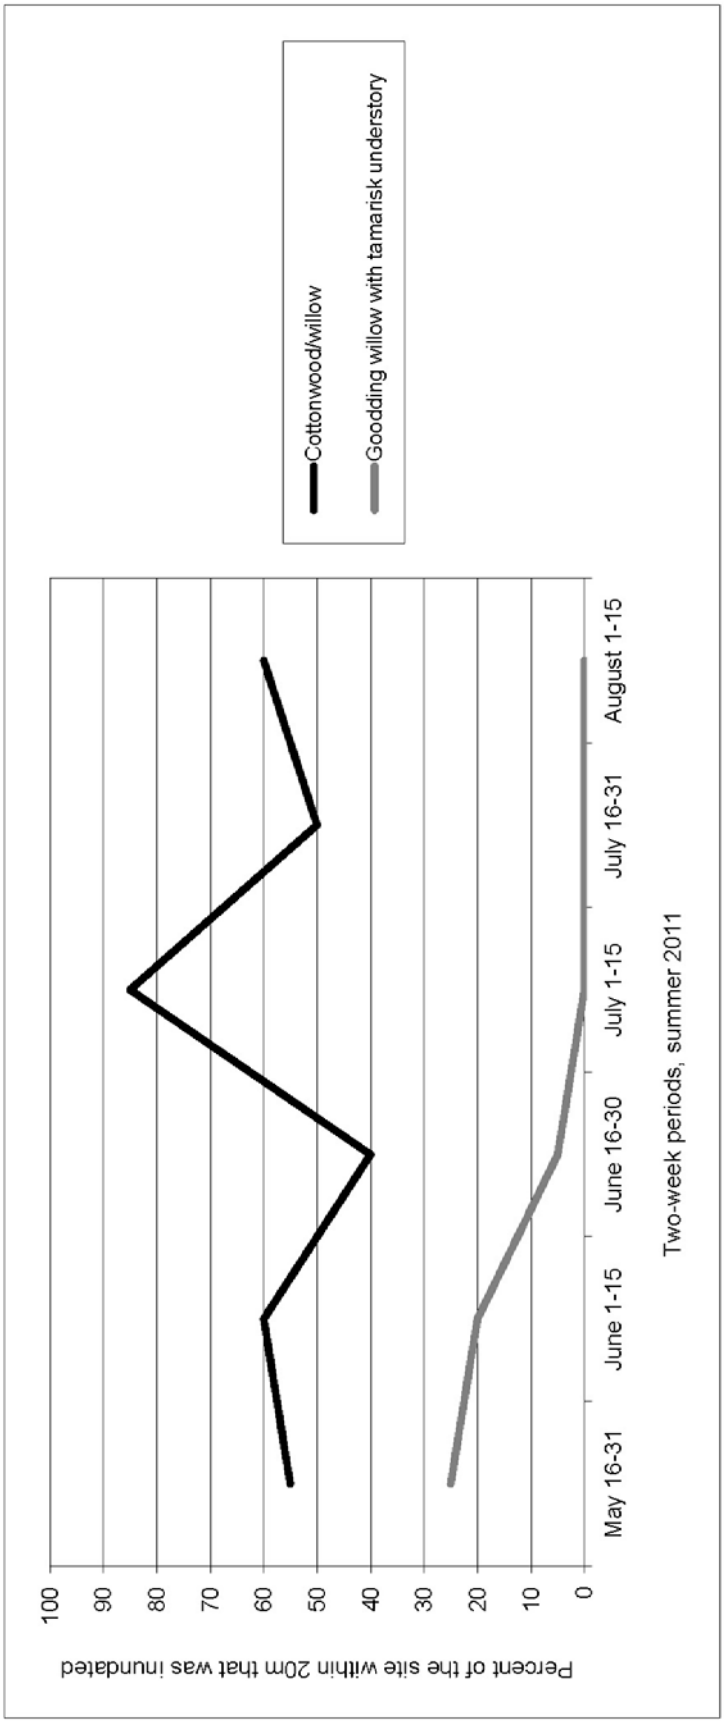

Figure 6.3. Percent of the area within 20 m of Southwestern Willow Flycatcher territories that contained standing water or saturated soil in various vegetation types, lower Colorado River and tributaries, 2011. Cottonwood/willow = cottonwood-willow Type III, and Goodding willow with tamarisk understory = cottonwood-willow Type I. Data are summarized by two-week periods. Each vegetation type contained a single flycatcher territory. Data are presented as means for instances in which percent inundated was measured more than once in a given two-week period.

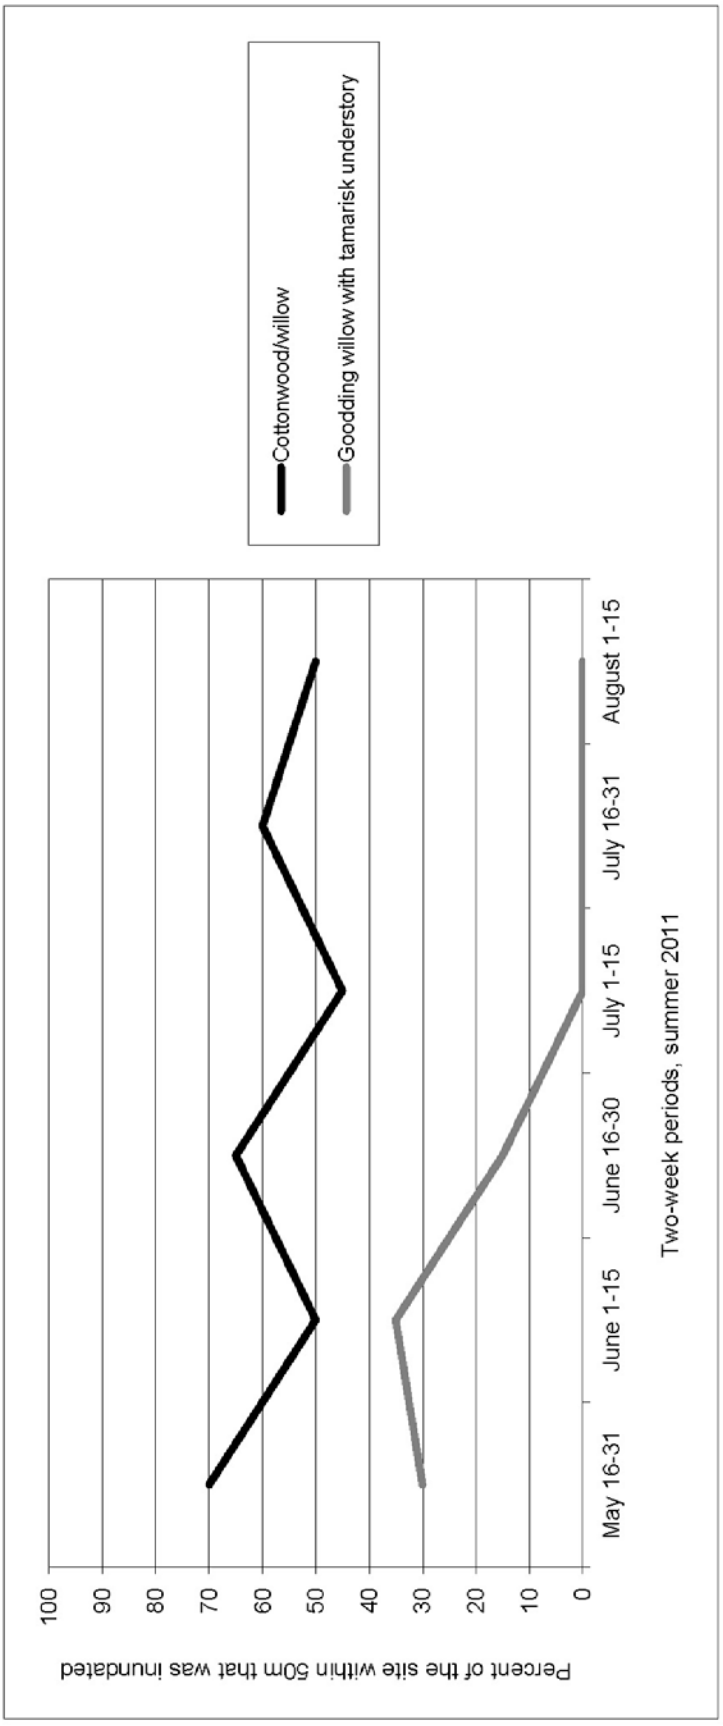

Figure 6.4. Percent of the area within 50 m of Southwestern Willow Flycatcher territories that contained standing water or saturated soil in various vegetation types, lower Colorado River and tributaries, 2011. Cottonwood/willow = cottonwood-willow Type III, and Goodding willow with tamarisk understory = cottonwood-willow Type I. Data are summarized by two-week periods. Each vegetation type contained a single flycatcher territory. Data are presented as means for instances in which percent inundated was measured more than once in a given two-week period.

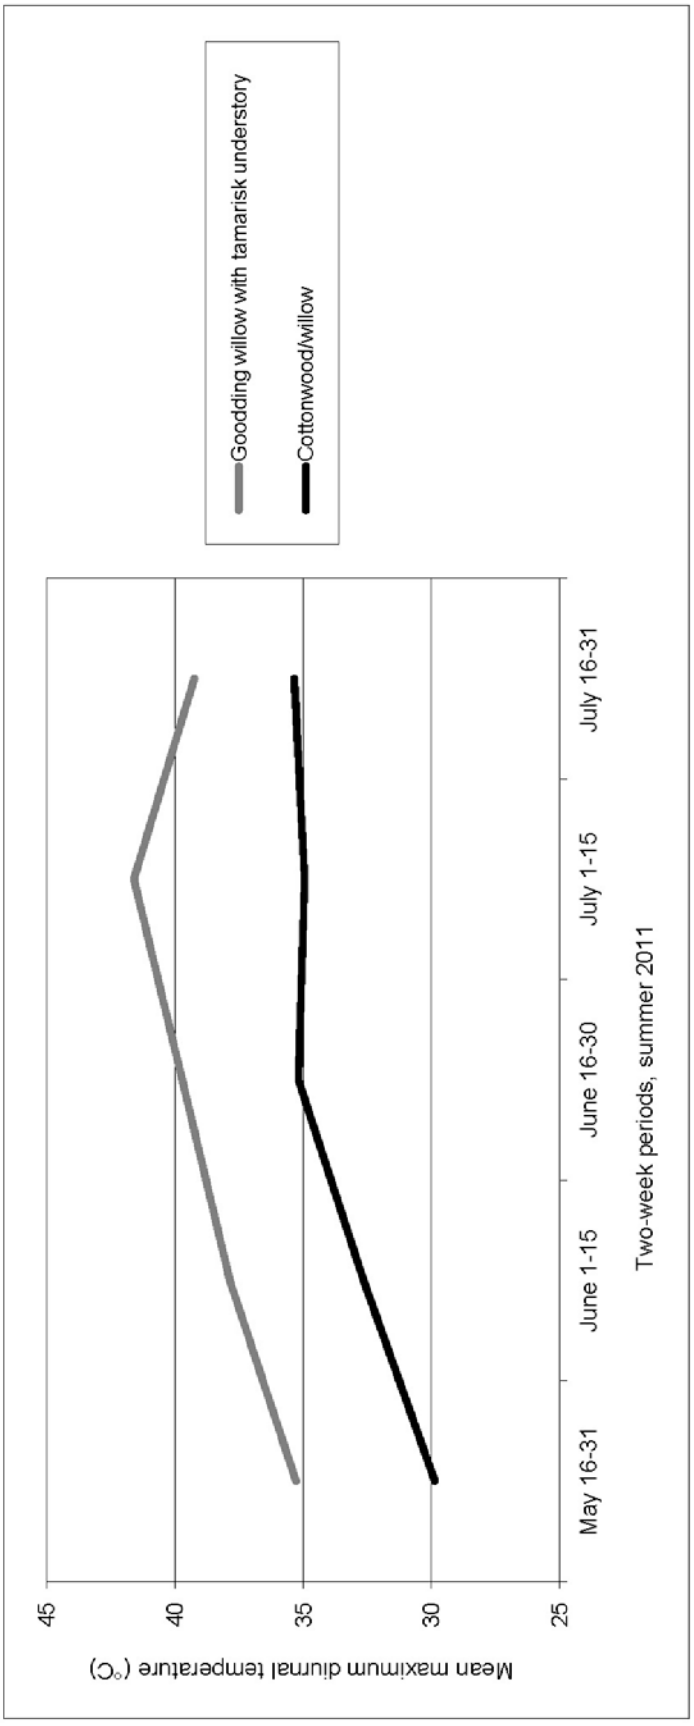

Figure 6.5. Mean maximum diurnal temperature at Southwestern Willow Flycatcher territories in various vegetation types, lower Colorado River and tributaries, 2011. Cottonwood/willow = cottonwood-willow Type III, and Goodding willow with tamarisk understory = cottonwood-willow Type I. Data are summarized by two-week periods.

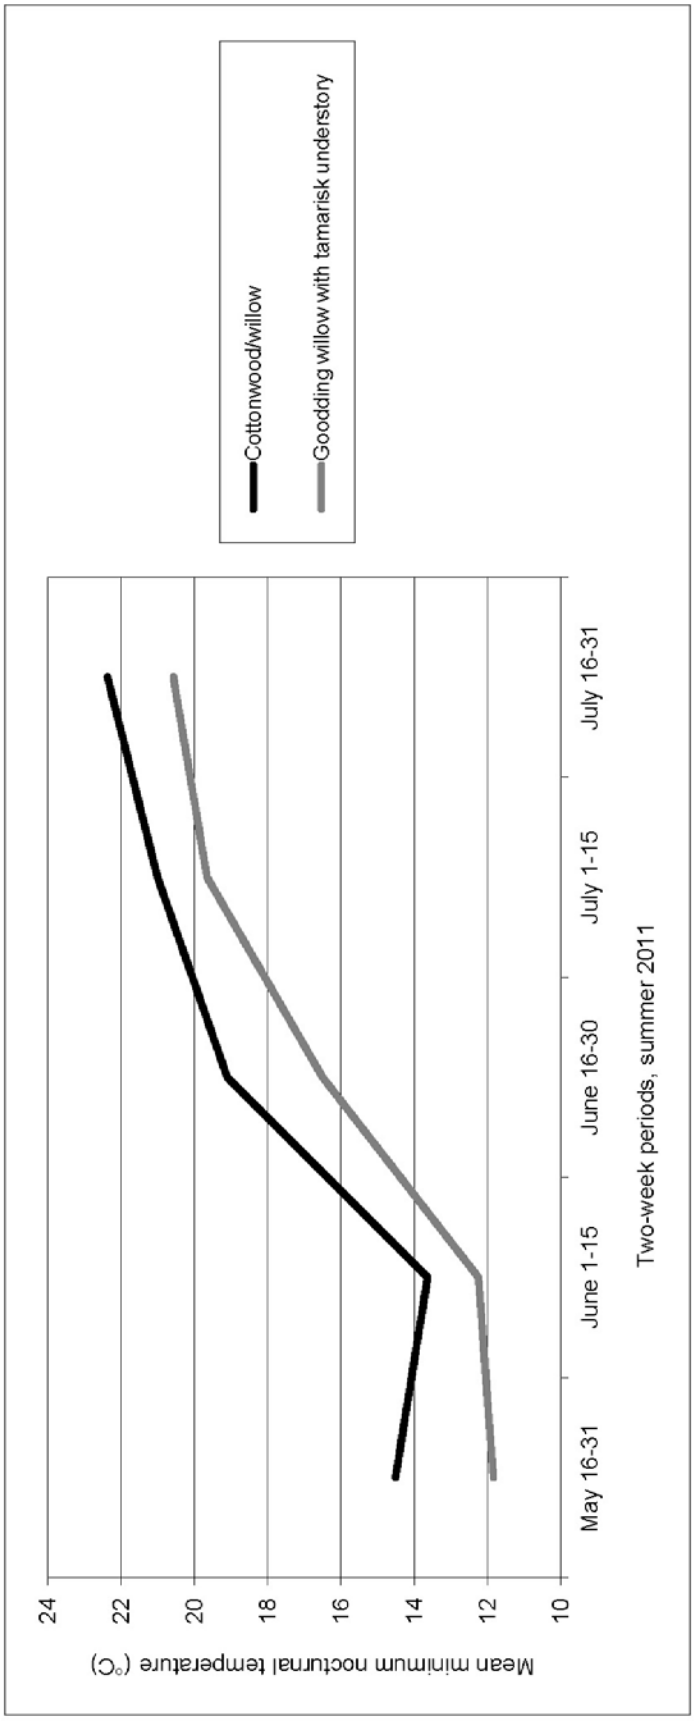

Figure 6.6. Mean minimum nocturnal temperature at Southwestern Willow Flycatcher territories in various vegetation types, lower Colorado River and tributaries, 2011. Cottonwood/willow = cottonwood-willow Type III, and Goodding willow with tamarisk understory = cottonwood-willow Type I. Data are summarized by two-week periods.

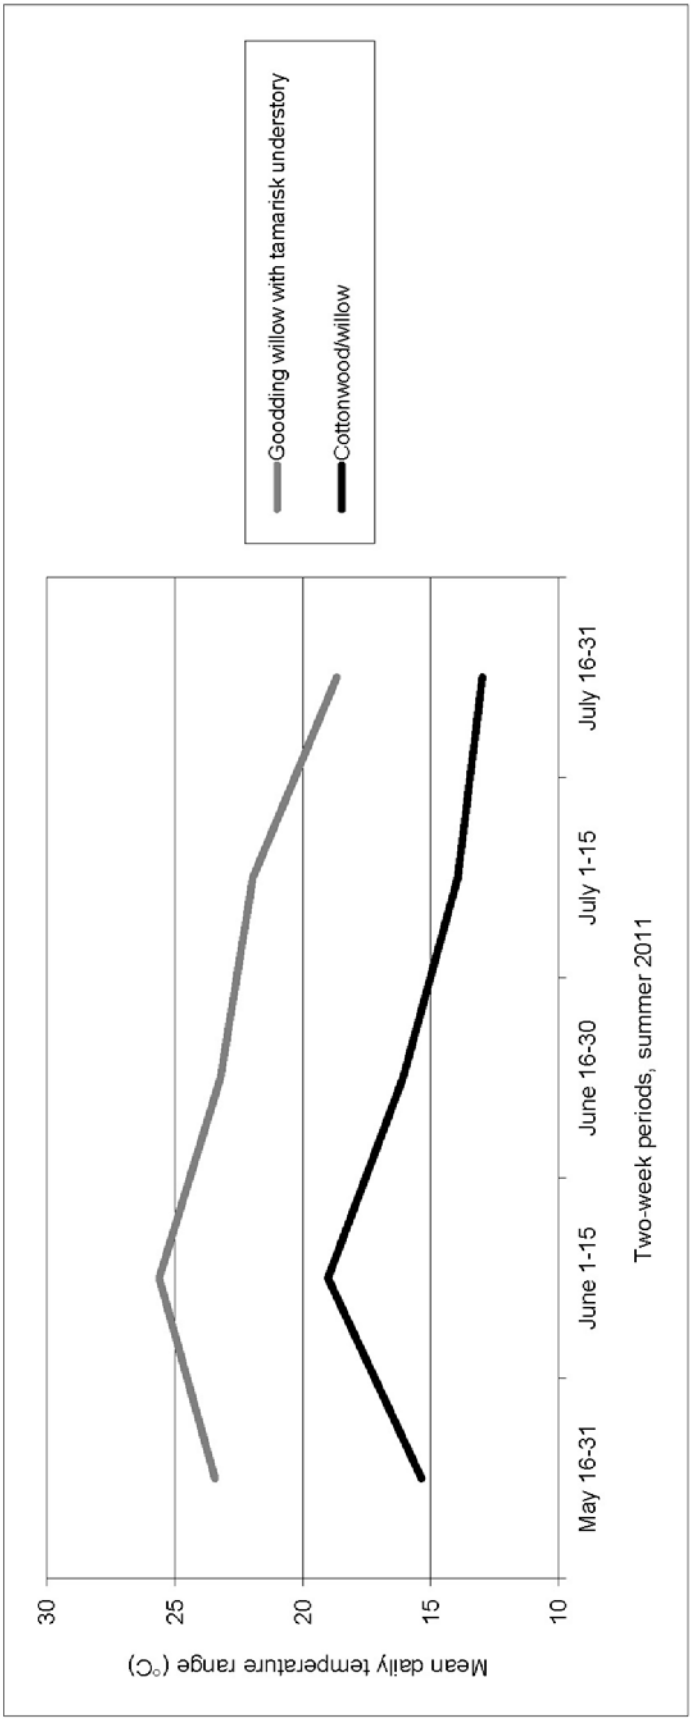

Figure 6.7. Mean daily temperature range at Southwestern Willow Flycatcher territories in various vegetation types, lower Colorado River and tributaries, 2011. Cottonwood/willow = cottonwood-willow Type III, and Goodding willow with tamarisk understory = cottonwood-willow Type I. Data are summarized by two-week periods.

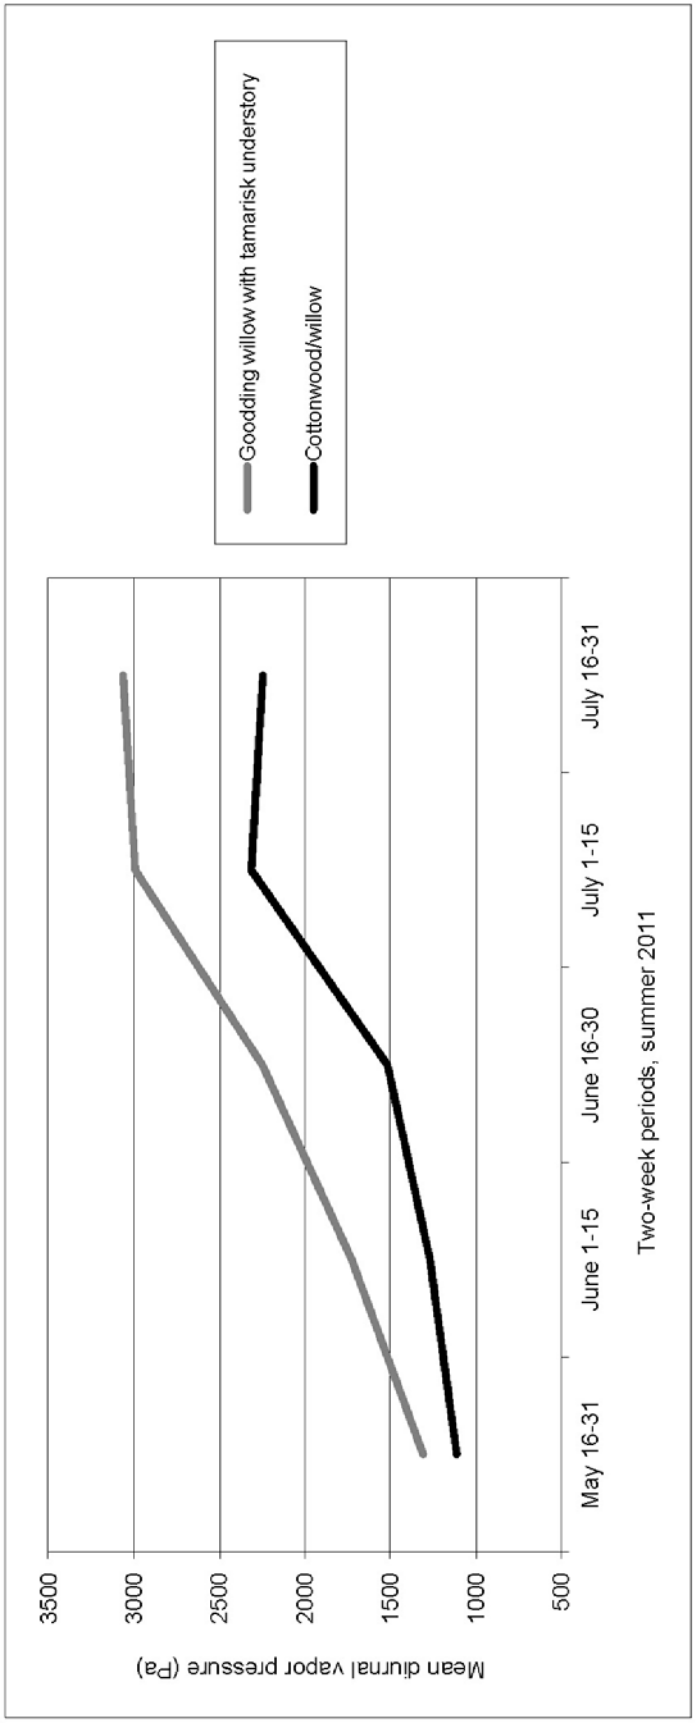

Figure 6.8. Mean diurnal vapor pressure at Southwestern Willow Flycatcher territories in various vegetation types, lower Colorado River and tributaries, 2011. Cottonwood/willow = cottonwood-willow Type III, and Goodding willow with tamarisk understory = cottonwood-willow Type I. Data are summarized by two-week periods.

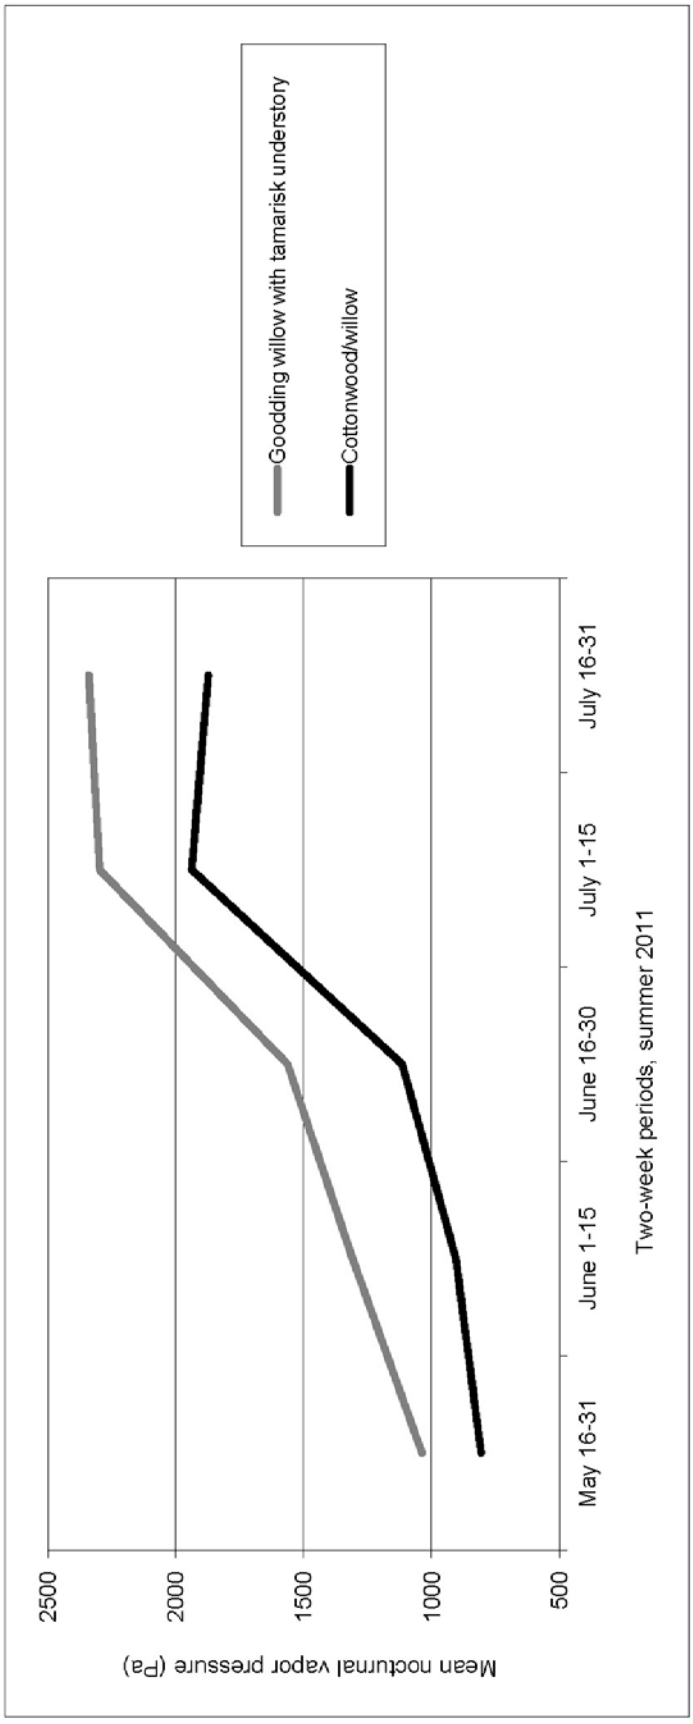

Figure 6.9. Mean nocturnal vapor pressure at Southwestern Willow Flycatcher territories in various vegetation types, lower Colorado River and tributaries, 2011. Cottonwood/willow = cottonwood-willow Type III, and Goodding willow with tamarisk understory = cottonwood-willow Type I. Data are summarized by two-week periods.

Both vegetation types exhibited moist soil conditions at some point during the breeding season. Goodding willow with tamarisk understory had high soil moisture content at the beginning of the breeding season and standing water within the territory through late June. The inundated percentage of the surrounding area declined steadily through May and June, and distance to surface water was over 300 m in July and August. Cottonwood/willow had consistently high soil moisture, and the inundated percentage of the surrounding area was at least 50% throughout the breeding season.

Mean daily maximum temperatures spanned a range of ~5°C among habitat types. Daily minimum temperatures showed a smaller range of <3°C. The daily temperature range in cottonwood/willow was consistently smaller than in Goodding willow with tamarisk understory. Vapor pressure increased through the end of July for both habitat types and was higher in Goodding willow with tamarisk understory than in cottonwood/willow.

DISCUSSION

The limited data collected in 2011 preclude any meaningful comparison between habitat types and any summary of overall microclimate characteristics in flycatcher territories. Data collected in 2011 will be added to data collected in prior years for a combined analysis to be presented in the summary report in 2012.

Chapter 7

HABITAT MONITORING: PARKER TO IMPERIAL DAMS

INTRODUCTION

Southwestern Willow Flycatcher nests and breeding territories are typically located near rivers, streams, and open water (Sogge and Marshall 2000) or over wet soil (Flett and Sanders 1987, Harris et al. 1987, Harris 1991). Nest substrate plants are often rooted in or overhang standing water. Although the association between breeding flycatchers and open water or wet soil is widely recognized by managers and scientists alike, the exact nature of the association is poorly quantified. Water may be a direct environmental cue for flycatcher nesting behavior or it may be the ultimate cause of proximate factors such as vegetation composition and structure, prey base, and microclimate.

Anthropogenic or natural modifications to surface water resources (i.e., fluvial hydrology and geomorphology) can modify existing and potential flycatcher breeding habitat and therefore have the potential to modify flycatcher abundance, distribution, and nesting success (Graf et al. 2002). For example, nine flycatcher territories at San Marcial on the middle Rio Grande in New Mexico exhibited a near absence of nesting attempts in 1996 when a combination of drought, upstream dam operations, and upstream withdrawals for irrigation removed all surface water (Johnson et al. 1999). This was in contrast to previous (1994, 1995) and subsequent (1997) years when active nests were documented at the site, with the river flowing in those years. A nearby control site that contained water exhibited multiple nesting attempts during all four years, leading Johnson et al. (1999) to suggest that the presence of water was a fundamental requirement for nesting. A similar pattern was observed along the Gila River in Arizona when decreased streamflow from 2002 to 2004 coincided with the number of flycatcher territories declining by nearly half each year (Munzer et al. 2005). Since 2004, flows within the Gila River have been greater and more consistent, and correspond with a continuing increase in flycatcher territories (14 to 97) from 2004 to 2009 (Graber and Koronkiewicz 2009b).

Flow characteristics of the lower Colorado River have been modified by numerous dams and irrigation withdrawals (Rosenberg et al. 1991). The river reach between Parker Dam and Imperial Dam is regulated by releases from Parker Dam, which has been in operation since 1939. Existing riparian habitat in the Parker to Imperial reach has likely adjusted to historical water release patterns from Parker Dam and appears to be in a stable or declining condition (LCR MSCP 2004). Implementation of the Secretarial Implementation Agreements/California 4.4 Plan (hereafter SIAs) by Reclamation would change the point of diversion for up to 400,000 acre-feet of California apportionment water for up to 75 years (USFWS 2001). The point of diversion, previously located below Parker Dam at Imperial Dam, would change to a point above Parker Dam, resulting in lower water levels in the river between Parker and Imperial. The change in point of diversion was scheduled to begin in 2002.

River flow changes related to the change in point of diversion have the potential to further modify riparian habitats below Parker Dam, habitats that are presently considered potentially suitable for willow flycatcher (USFWS 2001:47). Reclamation (2000) estimated that implementation of the SIAs will cause a drop in floodplain groundwater levels of 1.55 feet (0.47 m) or less. As a result, 372 acres (151 ha) of occupied[1] Southwestern Willow Flycatcher habitat could lose their moist soils. This loss could influence plant species composition (loss of cottonwood and willow) and structure (loss of vegetation volume) over an undetermined length of time. In addition, Reclamation estimated that 5,404 acres (2,187 ha) of

[1] As per the USFWS, occupied Southwestern Willow Flycatcher habitat is defined as patches of vegetation that are similar to and contiguous with areas where willow flycatchers were detected after 15 June in any year since surveys began in 1996.

potential flycatcher habitat could be influenced by the drop in groundwater level. These changes may affect the distribution, abundance, occupancy, and prey base of Southwestern Willow Flycatchers in the Parker to Imperial reach.

In 2004, Reclamation completed a pilot year of habitat monitoring by deploying temperature/humidity data loggers at several sites in the Parker to Imperial reach. Reclamation then initiated a more comprehensive, long-term study in 2005 for the purpose of addressing how the above hydrological changes might affect riparian habitats along the Parker to Imperial reach. The objective is to monitor 151 ha (372 acres) of occupied Southwestern Willow Flycatcher habitat between Parker and Imperial Dams for 10–15 years to determine how microclimate, vegetation, and groundwater conditions might be affected by the SIAs water transfer actions. Monitoring did not commence until after diversions started; therefore, antecedent conditions are unknown and monitoring analyses focus on detecting change through time rather than comparing current conditions to a baseline. An additional objective was to compare microclimate characteristics of sites in the Parker to Imperial reach with those at flycatcher breeding areas. This analysis was completed in previous years and is not repeated here. This chapter reports the results of habitat monitoring to date.

METHODS

In 2005, we selected a subset of sites that are currently surveyed for the presence of willow flycatchers for inclusion in the habitat monitoring study. We chose 11 sites distributed along the Parker to Imperial reach that are reasonably accessible, and where we believed groundwater levels were influenced primarily by river levels and not by outside sources such as irrigation return flows. Chosen sites equated to at least 75.3 ha (186 acres) on the California side of the lower Colorado River and at least 75.3 ha (186 acres) on the Arizona side. We also chose four control sites, two above Parker Dam and two below Imperial Dam, to distinguish any changes in microclimate, groundwater, or vegetation caused by water transfer actions from those caused by fluctuations in climate or rainfall. The 11 test sites are Ehrenberg, Three Fingers Lake, Cibola Lake, Walker Lake, Paradise, Hoge Ranch, Rattlesnake, Clear Lake, Ferguson Lake, Ferguson Wash, and Great Blue Heron, and the four control sites are Blankenship Bend, Havasu NE, Mittry West, and Gila Confluence North (Figure 7.1). We monitored these same 15 sites from 2005 to 2011. In August of 2006, we initiated habitat monitoring within a consistently occupied breeding site at Topock Marsh to obtain groundwater levels and patterns with which we can compare results obtained at the habitat monitoring sites. The analysis comparing Topock to the 15 habitat monitoring sites was completed in previous years and is not repeated here.

Temperature/Humidity Loggers

In 2005, we deployed HOBO H8 Pro (Onset Computer Corporation, Pocasset, MA) temperature/humidity data loggers at several locations within each site selected for habitat monitoring. All loggers collected data at 15-minute intervals and were placed in inverted plastic containers and camouflaged as described in Chapter 6. All 60 logger locations selected in 2005 were retained in 2006. Two additional data loggers were installed in the Topock Marsh monitoring site in August 2006. A portion of Gila Confluence North, one of the control sites below Imperial Dam, burned in December 2006. As a result of the fire, all vegetation at one HOBO location at the site was killed, and vegetation at another HOBO location was dramatically reduced. These two HOBOs were replaced in May 2007 with HOBOs at new locations within unburned portions of the site.

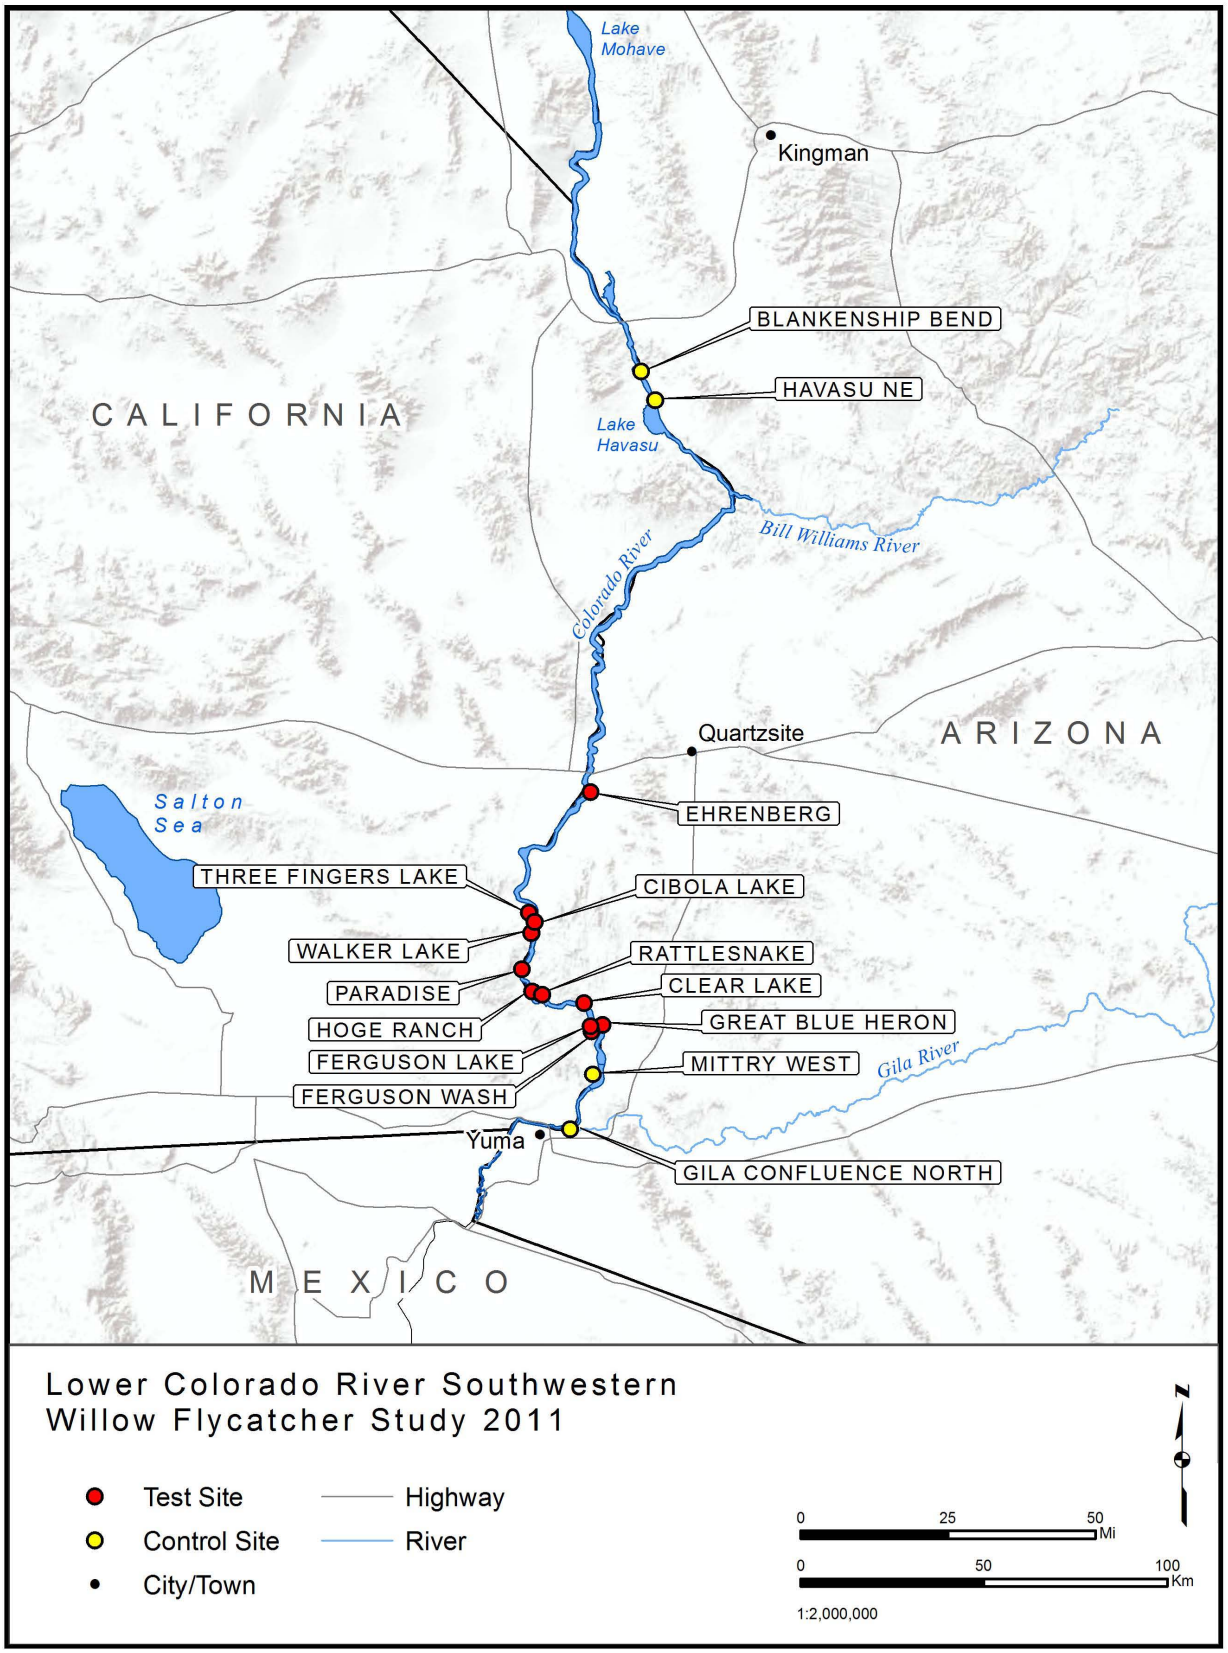

Figure 7.1. Locations of test and control sites, habitat monitoring study, 2005–2011.

HOBO loggers have been downloaded two or three times per year since installation. At each download, we examined the data to determine if there are any problems with data logger function. Data loggers were replaced whenever a potential problem with the sensors was detected. Battery level was also checked at each download, and the battery was replaced if needed.

Soil Moisture Measurements

Soil moisture beneath each HOBO logger was measured and recorded using a hand-held ThetaProbe ML2x coupled to an HH2 Moisture Meter Readout (Macaulay Land Use Research Institute, Aberdeen, UK, and Delta-T Devices, Cambridge, UK, respectively). Soil moisture measurements were collected during each presence/absence survey between 15 May and 25 July and when HOBO data were downloaded. Soil moisture measurements, percent of the area containing inundated or saturated soil, and distance to water were recorded as described in Chapter 6.

Vegetation Measurements

We completed vegetation measurements, following the methods described in Chapter 5, at each HOBO location after flycatcher surveys were completed in late July. All HOBO loggers were also downloaded at this time. Vegetation measurements were completed at the same locations as in 2005–2010 with the exception of Gila Confluence North, where vegetation measurements were collected at the two new HOBO locations established in 2007.

Groundwater Measurements

Piezometers were installed in May–August 2005 near each of the 15 sites selected for habitat monitoring. Analyses of groundwater data in previous years showed that releases from Parker Dam can be used to predict the groundwater level beneath the habitat polygons (e.g., McLeod et al. 2007, McLeod and Koronkiewicz 2009); consequently, these piezometers were removed in 2010. Analyses of the piezometer data are not repeated here. One additional piezometer was installed at Topock Marsh within occupied flycatcher habitat in 2006; see Chapter 8 for information regarding this piezometer.

Statistical Analyses

Microclimate

The following values were calculated for all 15 habitat monitoring sites:

- Mean soil moisture from plot center to 2.0 m from plot center
- Mean maximum diurnal temperature
- Mean minimum nocturnal temperature
- Mean daily temperature range (diurnal maximum minus nocturnal minimum)
- Mean diurnal vapor pressure
- Mean nocturnal vapor pressure

The diurnal and nocturnal periods were determined from the daily sunrise and sunset times reported for the region by the National Weather Service (2011).

We assigned all plots as a control site (above Parker Dam or below Imperial Dam) or as a test site (between Parker and Imperial). We analyzed between-year differences in humidity and soil moisture values within these two groups using linear mixed models and analyzed the between-year differences among the test sites compared to the control sites using repeated measures linear mixed models. These analyses were restricted to 1 June–1 August. Analyses were conducted using SAS® Version 9.2 (SAS Institute 2009).

Vegetation

We analyzed the between-year differences among the test sites compared to the control sites using repeated measures linear mixed models for canopy height, canopy closure, percent woody ground cover, three categories of stem sizes for both live and dead stems, the percentage of each stem size category that consisted of live stems, and the percentage of the basal area within the plot that consisted of native vegetation. In prior years we used repeated measures ANOVA for these analyses; however, repeated measures ANOVA excludes cases with missing values whereas linear mixed models allow for the inclusion of all data. We also used repeated measures linear mixed models to examine foliage density for live and dead vegetation summed over all height intervals. These analyses and all descriptive statistics were produced using SPSS® Version 16.0 (SPSS Inc.) software. We excluded vertical foliage density measurements at 5 m from plot center from the analysis so as to have comparable data across years.

RESULTS

Temperature/Humidity Logger Maintenance

All HOBO loggers were downloaded at the beginning and end of the 2011 field season. Four loggers had fallen to the ground over the winter because of sun damage to the logger housing. Five loggers that were in place over the winter had bad humidity sensors but useable temperature data, and one logger failed to collect data. Of the HOBO loggers in place May–August 2011, three failed to collect data, four had faulty humidity data, and four fell to the ground. Data from fallen loggers were not used in the analysis.

Microclimate

2011 Microclimate Descriptive Statistics

Soil moisture, temperature, and vapor pressure parameters from the 15 study sites monitored in 2011 exhibited substantial variation among sites (Table 7.1). Soil moisture varied from a low of 140.9 mV at Ferguson Wash to a high of 939.4 at Mittry West.

Mean maximum diurnal temperatures ranged from a low of 37.4^{o}C at Rattlesnake to a high of 48.2^{o}C at Cibola Lake. Mean minimum nocturnal temperatures ranged from a low of 15.1^{o}C at Gila Confluence North to a high of 20.0^{o}C at Three Fingers Lake. Mean daily temperature range varied from 19.5^{o}C at Ferguson Lake to 28.9^{o}C at Paradise.

Mean diurnal vapor pressure was lowest at Blankenship Bend (1106.6 Pa) and highest at Three Fingers Lake (1953.5 Pa). Mean nocturnal vapor pressure was lowest at Ferguson Wash (1080.9 Pa) and highest at Three Fingers Lake (1849.7 Pa).

Between-year Comparisons of Microclimate Characteristics

All microclimate characteristics varied significantly over time at test sites (Ehrenberg, Three Fingers Lake, Cibola Lake, Walker Lake, Paradise, Hoge Ranch, Rattlesnake, Clear Lake, Ferguson Lake, Ferguson Wash, and Great Blue Heron; Table 7.2). At control sites (Blankenship Bend, Havasu NE, Mittry West, and Gila Confluence North), mean minimum nocturnal temperature varied significantly over time, along with measures of soil moisture and humidity. Neither test nor control sites showed a unidirectional change in any of the microclimate measures in 2005–2011 (Figures 7.2–7.7), although both measures of humidity showed a generally decreasing trend at both test and control sites since 2006. The changes over time differed between test and control sites for soil moisture, mean diurnal vapor pressure, and mean nocturnal vapor pressure (right-most column of Table 7.2).

Soil moisture fluctuated among years at both test and control sites, but the patterns did not mirror one another (Figure 7.2). Between 2005 and 2006, soil moisture decreased more dramatically at control sites than at test sites, while between 2007 and 2008, soil moisture decreased at control sites but rose at test sites. Between 2009 and 2010, soil moisture decreased at test sites but rose at control sites. Diurnal vapor pressure rose more sharply at test sites than at control sites between 2005 and 2006 and then fell more sharply at test sites than at control sites between 2006 and 2007 (Figure 7.6), and nocturnal vapor pressure also showed larger fluctuations at test sites than at control sites.

Vegetation Measurements

Vegetation characteristics varied widely both between and within the selected habitat monitoring sites (Table 7.3). Average canopy height ranged from 3.3 m (Three Fingers Lake) to 9.8 m (Ehrenberg), and average canopy closure ranged from 66.9% (Ehrenberg) to 98.6% (Clear Lake). Measures of other habitat characteristics were similarly variable. Vertical foliage profiles for each site are shown in Figure 7.8. Sites typically exhibited the densest foliage within 3–5 m of the ground, and the majority of vegetation within 2–3 m of the ground typically consisted of dead branches.

Between-year Comparisons of Vegetation Characteristics

Many vegetation variables varied between years within the test and control groups (Table 7.4), but none of the variables exhibited change in a consistent direction over time (Figures 7.9–7.24). There was a significant interaction between year and location (meaning that the change between years among test sites was significantly different from the change at control sites) for woody ground cover ($P = 0.004$), number of live stems ≤2.5 cm dbh ($P = 0.043$), number of dead stems ≤ 2.5 cm dbh ($P = 0.040$), percent of live stems ≤2.5 cm dbh ($P = 0.022$), and dead vertical foliage hits ($P = 0.003$). Average woody ground cover increased at control plots between 2005 and 2006 and then decreased in 2007, while it did not change at test plots across those years. Overall, the number of live stems ≤2.5 cm dbh decreased through time at both test and control plots (Figure 7.12), while the number of dead stems ≤ 2.5 cm dbh decreased only at control plots (Figure 7.15), though there was considerable annual fluctuation for both variables. The percentage of live stems increased at control plots but decreased at test plots (Figure 7.18). The amount of dead vertical foliage hits increased through time at both test and control plots, but increased more rapidly at test plots (Figure 7.23).

DISCUSSION

Microclimate

Between-year Comparisons of Microclimate Characteristics

Comparisons of microclimate characteristics among years in 2005–2011 at the habitat monitoring sites indicated hotter and more humid conditions in 2006 than in the other years and cooler conditions in 2009. The interannual changes in temperature were similar between test and control sites, suggesting that these changes were regional rather than being influenced by local conditions. The interannual changes in soil moisture in 2005–2006, 2007–2008, and 2009–2010 were not similar between test and control sites, with soil moisture declining more sharply at the control sites during the first two periods and then rising sharply during the third. This suggests that local conditions, in addition to regional climate, may have influenced soil moisture. However, the role of river flows in influencing soil moisture is unclear, given that no strong relationship was found between piezometer levels and soil moisture (McLeod and Koronkiewicz 2009). Although vapor pressure fluctuated more sharply between years at test versus control sites, both test and control sites exhibited fluctuations in vapor pressure that were consistent with the annual fluctuations in dew point recorded at the Needles, California weather station (Coop ID 46118; Figure 7.25). Thus, regional weather appears to have an overriding influence on humidity within both test and control sites.

Vegetation

Between-year differences across all sites were noted for many variables, but none showed unidirectional trends over time, suggesting there has been no overall, detectable change in vegetation. Many vegetation characteristics that varied over time showed parallel changes at control and test sites, suggesting either widespread yearly variation or observer variation between years.

Few variables showed changes that were specific to control or test sites, and several of those variables had marginally significant (> 0.01) *P*-values. Only woody ground cover and dead vertical foliage had *P*-values < 0.01. Ground cover did not differ from 2005 to 2007 at test locations but increased at control plots in 2006 and then decreased in 2007. It is not clear whether this represents actual changes in the amount of woody ground cover or whether it is a result of observer variation. Vertical foliage counts of dead vegetation have increased overall over the last several years at test plots, although there has been considerable yearly fluctuation, and the percentage of the vertical foliage that consists of live vegetation has dropped accordingly. The interannual fluctuations make it difficult to draw inferences about general trends in vegetation health. In addition, we have not recorded an increase in the number of dead stems, suggesting that there has been no noticeable increase in plant mortality (but see discussion of stem counts, below).

The pooling of all sites into a test vs. control analysis may obscure changes in vegetation at specific sites. For example, one vegetation plot at Ehrenberg contained a significant coyote willow component (98% of the total basal area) in 2005. The willow gradually died over the next several years until no live willow remained in 2009. Most of the vegetation along the LCR, including at the sites selected for habitat monitoring, consists primarily of tamarisk, which is less sensitive than willow to changes in water availability. Measurable changes in overall vegetation as a response to reduced groundwater levels may take several years to develop in tamarisk, or the tamarisk may change very little if at all.

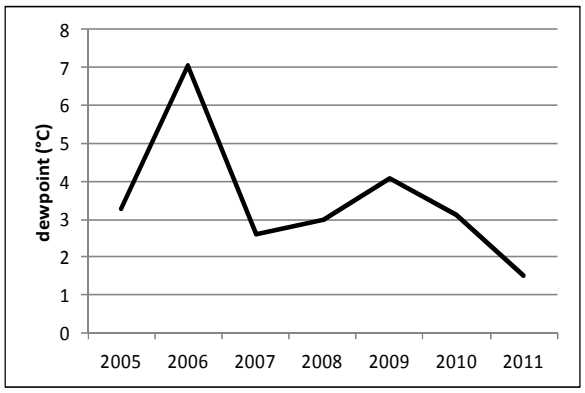

Figure 7.25. Mean dew point recorded at the Needles, California weather station, July and August, 2005–2011.

It has become apparent, after measuring the same vegetation plots for several consecutive years, that stem counts in very dense vegetation are inherently inaccurate and imprecise and can vary widely from year to year when there has likely been no appreciable change in stem density. Repeatability of stem counts depends on having a plot of fixed size. Each plot is divided into quadrants, with a rope having the 5-m distance (the edge of the plot) clearly marked extended in each cardinal direction from plot center. It can be nearly impossible to extend the rope flat or straight, introducing variability into the size of the plot. Even more problematic than this, however, is the inability of the observers, in very dense vegetation, to see the cardinal ropes from the center of the quadrant or to see the center of the plot from the edge to be able to envision an arc connecting the ends of two adjacent cardinal ropes and delineating the edge of the circular plot. Observers vary widely in their ability to estimate distance, and when reference points are not visible, it is very difficult to determine whether a stem near the edge of the plot falls within the plot or not. In 2009, we explicitly instructed observers to use a measuring tape to determine the distance from plot center for any stem for which inclusion in or exclusion from the plot seemed questionable.

This method should help reduce difficulties in producing repeatable stem counts but still depends on observers being able to tell when they are near the edge of the plot and taking the extra time to measure distance if the inclusion of a stem is in question. Another factor that inhibits accurate stem counts in dense vegetation is the difficulty in keeping track of which stems have been counted already and which have not. In 2009, we began using chalk to mark stems that had already been counted to try to minimize omission or double-counting of stems.

Given the difficulties in producing repeatable stem counts, absolute stem counts are likely not a suitable metric for detecting subtle changes in vegetation. The proportion of live stems may provide a more sensitive metric by which to detect change; the accuracy of this measure depends only on each observer counting live stems in a manner consistent with how s/he counts dead stems. Similarly, the proportion of live vertical foliage is likely to provide a more sensitive measure of changes in vegetation than do the absolute vertical foliage counts.

The detection of changes in vegetation as the result of the diversion of water at Parker rather than Imperial Dam is further hampered by the complete lack of vegetation measurements prior to the beginning of the diversion in 2002. Vegetation measurements did not commence until 2005, by which time it is possible that some changes in vegetation, particularly in sensitive species such as coyote willow, had already occurred as the result of decreasing flows from 2001 to 2005 (see Table 7.5). Other methods, such as analysis of satellite imagery, would have to be used to detect any changes in vegetation that might have occurred prior to 2005.

Groundwater Levels

Correlation of Piezometer Groundwater Levels with Soil Moisture Measurements

In previous years we correlated piezometer ground water levels and soil moisture measurements and found no strong linear relationship. The strongest relationships were found at sites that had the highest soil moisture values. This suggests that at sites where soil moisture is low, surface soil moisture content is not influenced by groundwater levels, and soil moisture measurements are unlikely to reflect any changes in water availability caused by changing river levels. We recommend discontinuing soil moisture measurements at Havasu NE, Cibola Lake, Clear Lake, Ferguson Wash, and Gila Confluence North, where soil moisture values are consistently below 600 mV.

Chapter 8

SURFACE HYDROLOGY, MICROCLIMATE, AND VEGETATION MONITORING: TOPOCK MARSH

INTRODUCTION

Monitoring of Southwestern Willow Flycatcher populations at Topock Marsh began in 1997, and data on number of flycatcher pairs and nest success are available for 1998–2011. The breeding population at Topock declined from a high of 29 pairs in 2004 to fewer than 10 pairs in 2007 and 2008. This decline prompted concern from USFWS about the flycatcher population at Topock, which was presumed to be the likely source population for any flycatchers that would colonize restoration areas on the lower Colorado River. USFWS and Reclamation initiated discussions after the breeding season of 2008 to identify habitat enhancement measures that could be implemented at Topock Marsh in an attempt to raise the number and productivity of flycatchers.

The affinity of breeding Southwestern Willow Flycatchers with standing water and saturated soil is noted consistently in the literature (e.g., Johnson et al. 1999, Munzer et al. 2005, McLeod et al. 2008a, Graber and Koronkiewicz 2009b), and flycatcher nests along the Middle Rio Grande that were above inundated or saturated soil all season produced more young per successful nest than nests that were above dry soil all season (Moore and Ahlers 2008). An examination of water levels within Topock Marsh from 1997 to the present shows that after 2004, water levels peaked at lower levels, high water levels were of shorter duration, and over-winter lows were lower than was the case prior to 2004 (Figure 8.1). Because of the influence of surface water on flycatcher occupancy and productivity, USFWS and Reclamation developed a plan to pump water into a portion of the flycatcher habitat at Topock Marsh.

Two adjacent areas within Topock, known as In Between and 800M, were selected in 2008 as the location for habitat enhancement via supplemental water delivery. The number of breeding flycatcher pairs in these areas declined steadily from 10 in 2004 to 0 in 2008, but the vegetation in the area had not changed markedly during that time (McLeod and Koronkiewicz 2010). The addition of surface water and saturated soil to this area might make it more attractive to flycatchers and increase nest success and productivity of any flycatchers that nest in the area. In addition, widespread inundation could make portions of In Between, 800M, and the surrounding area that typically had been dry during surveys since 2003 and not occupied by flycatchers more suitable for flycatcher occupancy.

Supplemental water delivery commenced in March 2011. We monitored hydrological, microclimate, and vegetation conditions at In Between, 800M, and the adjacent area of Pierced Egg in 2009 and 2010 to assess baseline habitat conditions. We completed the same monitoring in 2011 during water delivery.

METHODS

Water Delivery

Over the winter of 2010–2011, the water delivery system was installed. The system consisted of a Crisafulli trailer pump, modified to be hydraulically driven and capable of moving approximately 41.6 m^3 (11,000 gallons) of water per minute, along with a 0.61 m (24 inch) diameter pipe carrying the water into the target area (In Between, 800M, and Pierced Egg) from the open water of Topock Marsh.

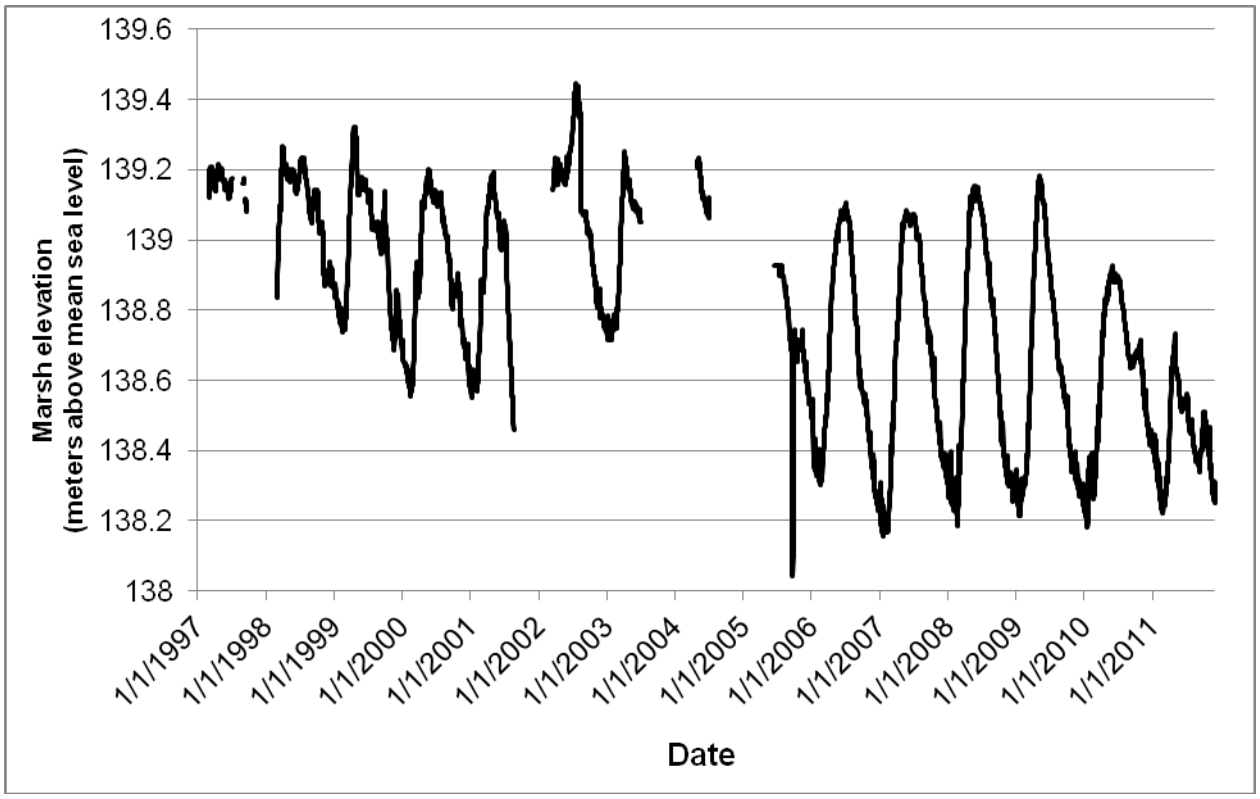

Figure 8.1. Marsh elevation (meters above mean sea level) measured at the South Dike at Topock Marsh, 1997–2011.

Surface Water Mapping

We mapped surface water at weekly intervals between 14 March and 21 July 2010. In 2011, we mapped water within the target area immediately prior to the initiation of water delivery on 1 March and for three days following the initial pumping. This provided baseline data on water levels, the maximum extent of water, and the longevity of water within the target area. We continued visiting In Between, 800M, and Pierced Egg at approximately weekly intervals through mid-July. During each visit, we traversed trails throughout each site and used GPS and aerial photographs to map the extent and depth of surface water within the sites. At the conclusion of each visit, we compiled our GPS points and field notes to prepare a hardcopy map of the sites, with areas of surface water and saturated soils delineated on the map and indexed to a key detailing the nature (e.g., pig wallow, open marsh, flooded forest) and depth of each wet area. All hardcopy maps were digitized after the field season using ArcGIS. From the digitized shapefiles, we calculated the percentage of the target area that contained surface water at each visit.

Groundwater Measurements

A 0.02 m (¾-inch) diameter shallow well, or piezometer, equipped with a pressure transducer and data logger was installed in 2006 in In Between at Topock Marsh as part of habitat monitoring between Parker and Imperial Dams (see Chapter 7). This piezometer is within the target area of water delivery and thus was left in place when the other piezometers used in the study were removed. This piezometer is described in McLeod et al. (2007) and has been downloaded approximately three times per year since installation. At each download we checked the battery level and function of the data logger. Batteries were replaced as necessary and data were examined to ascertain potential equipment malfunction.

Data Collection

A pressure transducer/data logger equipped with a vented cable collected data hourly at the piezometer. These devices measure and record pressure of the water column present in the well, and these pressure measurements are then converted into water levels (in distance below top of casing). With vented cables and data transfer ports there is no need to correct measurements for atmospheric pressure changes, and the data can be downloaded at the wellhead without disturbing the pressure transducer in the well.

During the initial installation of the pressure transducer, as well as at each data download thereafter, water level was manually measured in the piezometer using an electric water level sounder (Solinst-brand). This known water level was then used to program the pressure transducer with a baseline measurement from which all other automatically recorded water levels were calculated.

Data Validation

We have identified several potential sources of error in the water levels recorded by piezometers. We developed a rigorous protocol to validate each data download, determine if any errors exist with the data, and correct the raw data if possible. Specific sources of error are identified below.

Install Drift. Because piezometers are constructed such that the pressure transducer is almost the same diameter as the inside of the piezometer, removing and inserting the pressure transducers to change batteries can change the water levels in the piezometer temporarily but drastically.

Operational Drift. In rare cases, the accuracy of the data loggers can change in the time period between downloads.

Improper Setup. After downloading data, the data logger is reset for the next round of measurements. Conducting the startup procedure improperly can lead to errors; fortunately, most of these setup errors can be corrected. Common errors include mistakenly setting the type of reference used (i.e., recording water level elevation instead of depth), not resetting the starting water level reference value to the water level value measured manually in the field, and not restarting the data logger but continuing with the previous setup.

At each download, we compared the water level recorded by the piezometer with the manual measurement. We also checked the data logger parameters to determine whether the data logger was initialized properly. If a discrepancy >0.09 m (0.3 feet) existed between the data logger and the manual measurement, and this discrepancy could not be accounted for and corrected by examining the setup parameters and applying an appropriate correction factor, the data were not used for analysis.

Microclimate

In 2009, the In Between, 800M, and Pierced Egg polygons were stratified into use (occupied by flycatchers) and non-use (unoccupied by flycatchers) areas, as observed in 2003–2008. Use areas tend to be wetter than non-use areas and thus are presumably low-lying and more likely to be affected by water delivery into the habitat. We excluded the cattail marsh in the center of the 800M polygon from either the use or non-use areas. We superimposed a 25- x 25-m grid on a GIS software shapefile of the use and non-use areas, numbered the grid blocks, and selected blocks using a random number generator. We used the centroid of the selected block as the sample point and located each point in the field by navigating to the given coordinates using a Rino 110 GPS unit. We determined the exact location of each sample point by means of random number sequences as described in Chapter 6. All sample points used in 2009 were marked in the field with flagging that remained in place over the 2009–2010 and 2010–2011 winters,

allowing for relocation at the beginning of each subsequent season. We relocated each sample point in 2011 and redeployed a data logger in the same location. We used HOBO H8 Pro data loggers (see Chapter 6) to record temperature and humidity at each sample point at 15-minute intervals. Each logger remained in place until the end of the flycatcher breeding season. We collected soil moisture readings, as described in Chapter 6, below each data logger at bi-weekly intervals.

Vegetation

In late July of each year 2009–2011, at the end of the flycatcher breeding season, we collected vegetation measurements at each HOBO logger location. Vegetation plots were centered on the logger, and we collected the vegetation measurements described in Chapter 5, with the exception of stem counts. Given the relatively short time span between the implementation of water delivery and the subsequent vegetation measurements, any responses in vegetation are more likely to be apparent in canopy closure and vertical foliage density than in stem counts.

Data Analyses
